FORGET ROUTINE OPERATIONS AND CONCENTRATE ON GETTING THE BEST OUT OF THE SPECIMEN.

WITH THE EM 400, YOU CAN!

Whether you are photographing 1,2 Å lattice fringes, or looking at polymers at inadequate screen intensity, studying thick metal foils, or looking at more conventional specimens, the operational efficiency of the EM 400 gives you better results, easier and faster.

This is because, at whatever level of operation you are working, you are free to concentrate on getting the best out of the specimen. The instrument does the routine thinking for you, because so many of the routine procedures have been automated.

Here are just some of them: computer-type lens programming, monoknob focussing, highly efficient wobbler, accurate focus zoom, illumination zoom, automatic camera operation, automatic through-focus series, printout on plate of all important operating parameters... the list goes on and on.

Read the full story in the EM 400 brochure which also tells you about the 10^{-7} torr vacuum for unique specime protection, freedom from si problems, optical versatility with 7-lens optics, total systems concept for accessories... and many oth innovations.
The EM 400 is the first of generation.

Greater freedom on the job: Wild M5.

The stereomicroscope for maximum efficiency: the Wild M5. Built-in drum for magnifications from 1.5 to 200x, wide field of vision, adaptable for all illumination techniques and stereo-photomicrography. Most important of all: with the 32–270 mm working distance, you can manipulate the specimen whilst viewing. Test the Wild M5 and convince yourself.
Made in Switzerland, serviced the world over.

*

How long did it take you to get hold of this copy of *Nature?*

Half-an-hour ... a couple of days ... a week?

If it took longer than five minutes something is wrong.

Your library needs another copy, your department needs its own or that circulation list is simply too long.

Suggest an extra copy of *Nature* now, or fill in the Subscription Order Form overleaf.

* * *

The **Index** for 1974 is now on sale, price £1.65.

Binders for the journal are also available at £2.30 each, £6.25 for three (a year of *Nature* fits into three binders).

Postage is included in the above prices. Orders should be sent, accompanied by remittance, to Macmillan Journals Ltd, Brunel Road, Basingstoke, Hampshire, England.

M MACMILLAN PRESS

Guide to authors

● Articles are up to 3,000 words in ength with at most six displayed items (figures and tables) and may either be reports of major research developments in a subject or broader reviews of progress.

● Letters are brief reports of research of unusual and wide interest, not in general longer than 1,000 words; at most they have three or four displayed items (figures and tables).

● 'Matters Arising' permits occasional short discussion of papers that have previously appeared in *Nature*. There is a limit of 300 words.

Manuscripts may be submitted either to London or Washington. Three typed copies should be submitted, each including lettered copies of figures. Typing (including references) should be double spaced. The title should be brief and informative. Pages should be numbered. References, tables and figure legends should start on separate pages. Experimental detail vital to the paper yet which would interrupt the narrative is best placed in the figure legends. Units should conform to the Système International. Greek characters should be identified in the margin on their first appearance. Equations should occupy single lines if possible, exp (a) is preferred to e^a if 'a' is more than one character. Articles should be accompanied by an abstract of not more than fifty words listing the main conclusions.

References are indicated by superscripts in the text. See any contemporary *Nature* for style, but note:

(i) To refer to several references by the same author at once, only one reference number need be given.

(ii) Cite first and last pages.

Abbreviations should follow the *World List of Scientific Periodicals*, fourth ed. (Butterworth, 1963-65). Symposia are often difficult to refer to and only published or soon-to-be-published volumes should be mentioned in references. Their publisher and place of publication should be clearly indicated. 'Personal communication' and 'unpublished work' should be incorporated in the text.

Artwork should be sent with the manuscript. All artwork should be marked with the author's name. Line drawings should preferably be in Indian ink on heavy cartridge paper, although other materials are acceptable: thin, shiny, folded, torn or heavily handled material should be avoided. Matt rather than glossy photographs are preferred. Figures are usually reduced to one column width. The originals should be about as wide as a page of *Nature*. Figures, particularly maps, should contain nothing but essential material. It is preferred that the original be unlabelled, but with a copy containing lettering. Labelling on photographs should if possible be avoided entirely. We are always glad to see artwork for possible use on the cover, whether or not it is associated with a manuscript, but cannot guarantee the return of material.

In order to save on postal expenses we return only the top copy and artwork of manuscripts that we cannot publish.

A fuller guide appeared in *Nature* (**246**, 238; 1973).

Mobile charge carriers in photosynthesis—*R. A. Bogomolni and M. P. Klein* 88
Kinetic evidence for a conformational transition in rhodopsin—*J. G. Stewart, B. N. Baker and T. P. Williams* 89

Nature in Europe

UNTIL the beginning of 1975, European readers could only get *Nature* by surface mail, with delays of up to three weeks. During 1975, we have used air-speeded delivery for all European subscriptions. This has cut the delay to a few days. Postal rates applicable at the beginning of 1975 allowed us to do this for only £1.50 above the UK price.

Substantial increases in postal charges now make it impossible to keep the surcharge that low so, on renewal, European subscribers will be able to choose to pay either £35 (the same as the UK price) for a surface-mail subscription or £40 for an air-speeded subscription.

nature SUBSCRIPTION ORDER FORM

Subscription Department, Macmillan Journals Ltd, Brunel Road, Basingstoke, Hampshire, RG21 2XS England.

Please enter me for a year's subscription to **Nature** starting with the issue dated ....

Please note that subscriptions may take up to 4 weeks to process.

Surface Rates	UK	Australia	Europe	Japan	USA & Canada	Rest of the World

Unraveling the Mystery of Membranes

Methods in Membrane Biology

edited by **Edward D. Korn**

Volume 5
Transport

One property common to all cells is transport. Devoted solely to the study of this vital phenomenon, Volume 5 describes experimental methods, along with their theoretical bases, for examining the transport of molecules into bacterial and mammalian cells and thoroughly analyzes recent studies of electrical conductance in nerve tissues.

199 pages ISBN 0-306-36805-6 $19.50

Volume 4
Biophysical Approaches

In Volume 4, the instrumentation, theory, and practice of fluorescence spectroscopy and differential scanning calorimetry are surveyed as methods for determining the molecular arrangement of membrane lipids and proteins and the dynamics of their interrelationships. The work also summarizes the characteristics of synthetic bilayers as model membranes and procedural details for reconstituting membrane enzymatic activity at air—water phosphorized—protein monolayer.

298 pages ISBN 0-306-36804-8 $22.50

Membrane Biogenesis
Mitochondria, Chloroplasts and Bacteria

edited by **Alexander Tzagoloff**

Much of the current progress in understanding the mechanisms by which membranes are assembled and grow is based on three-widely studied membranes—those of mitochondria, chloroplasts, and bacteria. Describing recent research on the structure and genesis of these complex membranes, this volume offers new data on the organization of proteins and enzymes in membranes, the location of individual protein and lipid synthesis, and the infusion of proteins into membranes during growth.

460 pages ISBN 0-306-30825-8 $29.50

Biomembranes

Series editor: **Lionel A. Manson**
The Wistar Institute

Volume 7
Aharon Katzir Memorial Volume

edited by **Henryk Eisenberg, Ephraim Katchalski, and Lionel A. Manson**

Seventeen of the world's leading authorities discuss the results of their biomembrane research in this volume paying tribute to Aharon Katzir.

Contributors: Margareta Baltscheffsky. Ze'ev Barak. Britton Chance. D. Chapman. W. W. Cheng. Isidore S. Edelman. E. B. Margareta Ekblad. Ayala Frenkel. Ilan Freidberg. Charles Gilvarg. B. Z. Ginzburg. M. Ginzburg. Israel Goldberg. David Nachmansohn. Eberhard Neumann. Itzhak Ohad. W. Wilbrandt.

257 pages ISBN 0-306-39807-9 $24.50

Volume 6
Bacterial Membranes and the Respiratory Chain

N. S. Gel'man, M. A. Lukoyanova and D. N. Ostrovskii

An up-to-date survey of the field, this volume examines biochemical and physical methods used to study the molecular organization and function of biological membranes, with emphasis on bacterial membranes. Beginning with an outline of the morphology of the membrane system of bacteria, the authors evaluate the results of recent experiments on membrane structure and discuss analytical methods ranging from optical rotary dispersion, nuclear magnetic resonance, and spin probes, to electron microscopy.

261 pages ISBN 0-306-39806-0 $25.00

Articles should be accompanied by an abstract of not more than fifty words listing the main conclusions.

References are indicated by superscripts in the text. See any contemporary *Nature* for style, but note:

(i) To refer to several references by the same author at once, only one reference number need be given.

(ii) Cite first and last pages.

Abbreviations should follow the *World List of Scientific Periodicals*, fourth ed. (Butterworth, 1963-65). Symposia are often difficult to refer to and only published or soon-to-be-published volumes should be mentioned in references. Their publisher and place of publication should be clearly indicated. 'Personal communication' and 'unpublished work' should be incorporated in the text.

Artwork should be sent with the manuscript. All artwork should be marked with the author's name. Line drawings should preferably be in Indian ink on heavy cartridge paper, although other materials are acceptable: thin, shiny, folded, torn or heavily handled material should be avoided. Matt rather than glossy photographs are preferred. Figures are usually reduced to one column width.
The originals should be about as wide as a page of *Nature*. Figures, particularly maps, should contain nothing but essential material. It is preferred that the original be unlabelled, but with a copy containing lettering. Labelling on photographs should if possible be avoided entirely. We are always glad to see artwork for possible use on the cover, whether or not it is associated with a manuscript, but cannot guarantee the return of material.

In order to save on postal expenses we return only the top copy and artwork of manuscripts that we cannot publish.

Reader enquiry service xxii

At the end of last week we said goodbye to our News Editor of the past two years, John Hall, who goes to the *Daily Telegraph Magazine* as Assistant Features Editor. During his time at *Nature* he has, in particular, had a considerable influence on the design and layout of the journal. In his place we welcome Chris Sherwell, a journalist who joins us from the *Financial Times*.

Chemisorption and Magnetization

by P. W SELWOOD

Chemisorption and Magnnetization is essentially a completely revised and updated edition of the author's 1962 publication, *Adsorption and Collective Paramagnetism.* Professor Selwood, a pioneer and leading researcher in the use of magnetic methods in catalytic research describes in detail the experimental techniques and interpretation of results involved in using magnetic measurements to gain information about chemisorbed molecules on certain kinds of solid surfaces Though the treatment is on an advanced level, the wealth of detail and numerous examples make the book accessible to anyone with a basic knowledge of surface chemistry, heterogeneous catalysis, or solid state physics.

The method outlined here is applicable to ferromagnetic solids and especially to nickel metal; there is no restriction on the kind of adsorbate for which the method may be used. Basically, this method gives the number of adsorbent atoms primarily affected by the adsorbate molecule under almost any experimental conditions.

Marijuana and Health Hazards

Methodological Issues in Current Research

edited by JARED R. TINKLENBERG

Based on a conference sponsored by the Drug Abuse Council, Inc., this book gives particular attention to five areas of current concern and special interest — genetics, immunity, hormones, central nervous system damage, and psychiatric disturbances.

CONTENTS: **Genetics:** *A Falek,* Genetic Studies of Marijuana: Current Findings and New Directions *S. S Matsuyama,* Cytogenetic Studies of Marijuana. *M. A Stenchever,* Observations on the Cytogenetic Effects of Marijuana. Marijuana and Genetics· A Discussion. **Immunity:** *A. E. Munsen,* Marijuana and Immunity. *G. G. Nahas,* Effects of Marijuana Smoking and Natural Cannabinoids on the Replication of Human Lymphocytes and the Formation of Hypodiploid Cells. Marijuana and Immunity: A Discussion **Testosterone:** *R. M Rose,* Background Paper on Testosterone and Marijuana. *R. C. Kolodny,* Research Issues in the Study of Marijuana and Male Reproductive Physiology in Humans. *J. H Mendelson, J. Kuehnle, J. Ellingboe and T. F. Babor,* Effects of Marijuana on Plasma Testosterone. Marijuana and Testosterone A Discussion. **Central Nervous System:** *R L. Dornbush,* Marijuana and the Central Nervous system. *R. T. Jones,* Effects of Marijuana on the Mind. *H. B C Reed, Jr.,* Marijuana and Brain Dysfunction Selected Research Issues. Marijuana and the Central Nervous System· A Discussion. **Psychiatric Problems: R. E. Meyer,** Psychiatric Consequences of Marijuana Use: The State of the Evidence. *J H. Jaffe,* Psychiatric Consequences of Marijuana. Marijuana and Psychiatric Problems: A Discussion. Epilogue: *D X. Freedman,* Passions, Pot and Scientific Policy.

1975, 188 pp., $8 50/£4 50

Second Edition

The Plasma Proteins

Structure, Function, and Genetic Control

edited by FRANK W. PUTNAM

When the first edition of *The Plasma Proteins* was published some fifteen years ago, *Nature* hailed it as "a major contribution to the literature on proteins " The long-awaited second edition of *The Plasma Proteins* has now been completely rewritten by an international group of eminent contributors under the editorship of Frank W Putnam Incorporating all the major developments that have occurred within the last fifteen years, *The Plasma Proteins* (Second Edition) is the only comprehensive, integrated, up-to-date treatise on blood plasma proteins. It fully covers the structure, function, and genetic control of blood proteins, with special emphasis on their clinical relevance

CONTENTS OF VOLUME 1: *F. W. Putnam,* Perspectives — Past, Present, and Future. *F W. Putnam,* Alpha, Beta, Gamma, Omega — The Roster of the Plasma Proteins. *T. Peters, Jr.,* Serum Albumin. *K. Schmid,* 1—Acid Glycoprotein. *C.-B. Laurell and J. -O. Jeppsson,* Protease Inhibitors in Plasma. *F. W. Putnam,* Transferrin. *A. M Scanu, C. Edelstein, and P Keim,* Serum Lipoproteins. *H J. Muller-Eberhard.* The Complement System *M. D. Poulik,* B2-Microglobulin

Volume 1/1975, 488 pp., $37 50/£19 50, subscription price, $32.00

CONTENTS OF VOLUME 2: *F. W. Putnam,* Haptoglobin. *M D. Poulik and M. L. Weiss,* Ceruloplasmin *R. F. Doolittle,* Fibrinogen and Fibrin. *J. R. Clamp,* Structure and Function of Glycoproteins. *W. H. Fishman and G. J Doellgast,* Tissue-Derived Plasma Enzymes. *D. Gitlin and J. D. Gitlin,* Fetal and Neonatal Development of Human Plasma Proteins. *D Gitlin and J. D. Gitlin,* Genetic Alterations in the Plasma Proteins of Man. *R. F. Ritchie,* Automated Immunoprecipitation Analysis of Serum Proteins

Volume 2/1975, in preparation

Teratomas and Differentiation

edited by MICHAEL I. SHERMAN and DAVOR SOLTER

CONTENTS: **Introduction and Terminology:** *G. B Pierce,* Teratocarcinoma: Introduction and Perspectives *L. C. Stevens and G. B Pierce,* Teratomas· Definitions and Terminology *Embryo-Teratoma Relationships: L. C. Stevens,* Comparative Development of Normal and Parthenogenetic Mouse Embryos, Early Testicular and Ovarian Teratomas, and Embryoid Bodies. *C. F Graham, et al.,* Teratomas from Haploid and Diploid Parthenogenetic Mouse Embryos. *R L. Brinster,* Can Teratocarcinoma Cells Colonize the Mouse Embryo? *B Mintz, et al.,* Developmental and Experimental Potentialities of Mouse Teratocarcinoma Cells from Embroyoid Body Cores *N. Skreb and A. Svajger,* Experimental Teratomas in Rats. **Surface Antigens on Embryos and Teratomas:** *C. Babinet, et al.,* Expression of a Cell Surface Antigen Common to Primitive Mouse Teratocarcinoma Cells and Cleavage Embryos during Embryogenesis and Spermatogenesis *M. Edidin and L. Gooding,* Teratoma-Defined and Transplantation Antigens in Early Mouse Embryos *R. A. Miller, et al.,* Surface Antigens of Blastocyts-Derived Cell Lines. **Teratoma-Host Interactions:** *D. Solter, et al.,* Control of Teratocarcinogeneneşis. *T Bon, et al.,* Mutagenized Clones of a Pluripotent Teratoma Cell Line: Variants with Decreased Differentiation or Tumour-Formation Ability. Control of Differentiation of Embryonal Carcinoma Cells *G. R. Martin and M. J. Evans,* The Formation of Embryoid Bodies *In Vitro* by Homogeneous Embryonal Carcinoma Cell Cultures Derived from Isolated Single Cells *M. I. Sherman,* Differentiation of Teratoma Cell Line PCC4.azal *In Vitro.* **Properties of Embryonal Carcinoma Cells:** *I. Damjanov and D. Solter,* Ultrastructure of Murine Teratocarcinomas. *J Jami and J. E. Loeb,* Chromatin Properties of Mouse Primitive Teratocarcinoma Cells: Electrophoretic Comparison with Somatic Tissues of the Mouse. **Properties of Teratomas In Vitro:** *M F. James and G. R. Martin,* The Differentiation of Clonal Teratocarcinoma Cell Cultures *In Vitro J D. Hall,* The *In Vitro* Differentiation of Embryoid Bodies Produced by a Transplantable Teratoma of Mice *E. G. Bernstine and B Ephrussi,* Alkaline Phosphatase Activity in Embryonal Carcinoma and Its Hybrids with Neuroblastoma. *J. M. Lehman, et al.,* The Response of Murine Teratocarcinoma Cells to Infection with DNA and RNA Viruses **Bibliography.**

1975. 342 pp., $16.50/£8 60

Biology and Geology of Coral Reefs

Volume III: Biology 2

edited by O A JONES and R. ENDEAN

This four-volume treatise deals with many aspects of the biology (including zoology, botany, and microbiology), geography, geomorphology, and the geological history of coral reefs in most of the coraliferous seas of the world. It reviews current knowledge of major problems in these fields and summarizes modern views of these problems

CONTENTS: *W. K. Patton,* Animal Associates of Living Reef Corals *A. J. Bruce,* Shrimps and Prawns of Coral Reefs, with Special Reference to Commensalism. *A. M. Clark,* Echinoderms of Coral Reefs. *B. Goldman and F. H. Talbot,* Aspects of the Ecology of Coral Reef Fishes. *A. M Cameron,* Toxicity of Coral Reef Fishes *A. H. Banner,* Ciguatera: A Disease from Coral Reef Fish *R. Endean,* Destruction and Recovery of Coral Reef Communities. *F R. Fosberg,* Coral Island Vegetation. *J. Kikkawa,* The Birds of the Great Barrier Reef. *H R Bustard,* Turtles of Coral Reefs and Coral Islands. *H Heatwole,* The Ecology and Biogeography of Coral Cays.

1975, 488 pp., $37 50/£19 50; subscription price, $32 00

Estuarine Research

VOLUMES 1 and 2

Proceedings of the Second International Estuarine Conference held at Myrtle Beach, South Carolina, October 1973.

edited by L EUGENE CRONIN

From the Preface: "These publications are the first of a biennial series planned by the Estuarine Research Federation to present new information and concepts relating to the estuaries of the world. Volumes I and II contain the papers presented in the Sscond International Estuarine Research Conference, held by the Federation at Myrtle Beach, South Carolina in October of 1973. The Conference was cosponsored by the American Society of Limnology and Oceanography and by the Estuarine and Brackish Water Sciences Association

"Volume I contains papers on *Chemistry,* focused on the Cycling of Elements and Estuaries, *Biology,* including sessions on the Dynamics of Food Webs, Nutrient Cycling, Zooplankton, Nekton, and Benthos, and *The Estuarine System.* Volume II provides publications on *Geology,* with collections on Estuaries with Small Tidal Ranges, Intermediate Tidal Ranges, and Large Tidal Ranges, and an additional section on *Wide-Mouthed Estuaries.* It also includes new materials on *Engineering,* with emphasis on Use of Vegetation in Coastal Engineering and on Estuarine Dredging Problems and Effects."

VOLUME 1: CHEMISTRY, BIOLOGY AND THE ESTUARINE SYSTEM
1975, 750 pp., $31.50/£16.40

VOLUME 2: GEOLOGY AND ENGINEERING
1975, 602 pp., $27.50/£14 30
Set price for both volumes, *$50 00.*

Responses of Plants to Air Pollution

edited by J BRIAN MUDD and T T. KOZLOWSKI

A Volume in the PHYSIOLOGICAL ECOLOGY Series

From reactions at the subcellular level to effects on entire ecosystems, this volume, written by some of the world's leading researchers in the field, details the effects of air pollutants both individually and synergistically on the higher and lower plant groups. The comprehensive, authoritative, and well-documented treatment covers the anatomy, ecology, pathology, and biochemistry of plants in relation to air pollution.

CONTENTS *T. T Kozlowski and J. B. Mudd,* Introduction. *J. B. Mudd,* Sulfur Dioxide. *R. L. Heath,* Ozone. *C W. Chang,* Fluorides. *J. B. Mudd,* Peroxyacyl Nitrates. *O. C Taylor, C. R Thompson, D. T. Tingey and R. A. Reinert,* Oxides of Nitrogen *S L. Lerman and E. F. Darley,* Particulates *R A. Reinert, A. S Heagle, and W. W. Heck,* Plant Responses to Pollutant Combinations *W. W. Thomson,* Effects of Air Pollutants on Plant Ultrastructure. *P. R Miller and J. R. McBride,* Effects of Air Pollutants on Forests. *F. LeBlanc and D. N Rao,* Effects of Air Air Pollutants on Lichens and Bryophytes. *J. H. Bennett and A C. Hill,* Interactions of Air Pollutants with Canopies of Vegetation *M Treshow,* Interaction of Air Pollutants and Plant Disease *S. Rich,* Interactions of Air Pollution and Agricultural Practices

1975, 392 pp, $29.50/£15.35

N.B.: Postage plus 50c handling charge on all orders not accompanied by payment

Prices subject to change without notice.

24-28 Oval Road, London NW1 7DX

Circle No. 04 on Reader Enquiry Form.

Guide to authors

- Articles are up to 3,000 words in length with at most six displayed items (figures and tables) and may either be reports of major research developments in a subject or broader reviews of progress
- Letters are brief reports of research of unusual and wide interest, not in general longer than 1,000 words; at most they have three or four displayed items (figures and tables).
- 'Matters Arising' permits occasional short discussion of papers that have previously appeared in *Nature*. There is a limit of 300 words.

Manuscripts may be submitted either to London or Washington. Three typed copies should be submitted, each including lettered copies of figures. Typing (including references) should be double spaced. The title should be brief and informative Pages should be numbered. References, tables and figure legends should start on separate pages. Experimental detail vital to the paper yet which would interrupt the narrative is best placed in the figure legends. Units should conform to the Système International. Greek characters should be identified in the margin on their first appearance. Equations should occupy single lines if possible, exp (a) is preferred to e^a if 'a' is more than one character. Articles should be accompanied by an abstract of not more than fifty words listing the main conclusions.

References are indicated by superscripts in the text. See any contemporary *Nature* for style, but note:

(i) To refer to several references by the same author at once, only one reference number need be given.

(ii) Cite first and last pages.

Abbreviations should follow the *World List of Scientific Periodicals*, fourth ed. (Butterworth, 1963-65). Symposia are often difficult to refer to and only published or soon-to-be-published volumes should be mentioned in references. Their publisher and place of publication should be clearly indicated. 'Personal communication' and 'unpublished work' should be incorporated in the text.

Artwork should be sent with the manuscript. All artwork should be marked with the author's name. Line drawings should preferably be in Indian ink on heavy cartridge paper, although other materials are acceptable: thin, shiny, folded, torn or heavily handled material should be avoided. Matt rather than glossy photographs are preferred. Figures are usually reduced to one column width.
The originals should be about as wide as a page of *Nature*. Figures, particularly maps, should contain nothing but essential material. It is preferred that the original be unlabelled, but with a copy containing lettering. Labelling on photographs should if possible be avoided entirely. We are always glad to see artwork for possible use on the cover, whether or not it is associated with a manuscript, but cannot guarantee the return of material.

In order to save on postal expenses we return only the top copy and artwork of manuscripts that we cannot publish.

Nature in Europe

UNTIL the beginning of 1975, European readers could only get *Nature* by surface mail, with delays of up to three weeks. During 1975, we have used air-speeded delivery for all European subscriptions This has cut the delay to a few days. Postal rates applicable at the beginning of 1975 allowed us to do this for only £1.50 above the UK price.

Substantial increases in postal charges now make it impossible to keep the surcharge that low so, on renewal, European subscribers will be able to choose to pay either £35 (the same as the UK price) for a surface-mail subscription or £40 for an air-speeded subscription

Colour centres past, present and future—*P. D. Townsend* 293
Linkage disequilibrium between *H-2* and *t* complexes in chromosome 17 of the mouse—*C. Hammerberg and J. Klein* 296
Evidence for cell surface control of macronuclear DNA synthesis in *Stentor*—*N. de Terra* 300
The vegetation of Tertiary islands on the Ninetyeast Ridge—*E. M. Kemp and W. K. Harris* 303

LETTERS TO NATURE

Improved declination for transient X-ray source A0620-00—*J. Bieging and D. Downes* 307
X-ray sources and planetary nebulae—*M. Livio and G. Shaviv* 308
Qualitative features of synchrotron radiation in an inhomogeneous magnetic field—*G. Cavallo and A. Ventura* 309
Thorium in the spectrum of HR465—*C. R. Cowley, M. S. Allen and G. C L. Aikman* 311
Controlled artificial generation of geomagnetic pulsations—*B. J. Lipa, A. C. Fraser-Smith, O G. Villard, Jr and J. R. Storey* 311
Reality and nature of a Sun–weather correlation—*C. O. Hines and I. Halevy* 313
Conductivity and rectification in metal halide intervalence mixtures—*D. R Rosseinsky and R. E. Malpas* 314
Precise determination of critical features in radiohalo-type coloration of biotite—*C. Moazed, R. Overbey and R. M. Spector* 315
'1/*f* noise' in music and speech—*R. F. Voss and J. Clarke* 317
Developmental changes in suckling of rat pups—*W. G. Hall, C. P. Cramer and E. M. Blass* 318
Time resolution of acoustic signals by birds—*R. Wilkinson and P. E. Howse* 320
Inhibition of cortical evoked potentials and sensation by self-initiated movement in man—*D. Papakostopoulos, R. Cooper and H. J. Crow* 321
Methylmercury and selenium in umbilical cords of inhabitants of the Minamata area—*S. Nishigaki and M. Harada* 324
Investigation of cell lineage in bone using a chimaera of chick and quail embryonic tissue—*A. J. Kahn and D. J. Simmons* 325
Stimulation of *in vitro* somite chondrogenesis by procollagen and collagen—*R. A. Kosher and R. L. Church* 327
Early-labelled haem in erythroid and hepatic cells—*C. Z. Yannoni and S. H. Robinson* 330
Inversion of levels of human T and B cells in early pregnancy—*A. J. Strelkauskas, B S. Wilson, S. Dray and M Dodson* 331
Inhibition of mammalian cytotoxic cells by phosphatidylcholine and its analogue—*L. D. Frye and G. J. Friou* 333
Immunological restoration of both thymectomised and athymic nude mice by a thymus factor—*S. Ikehara, Y. Hamashima and T. Masuda* 335
Calcium-dependent stimulation of platelet aggregation by PGE_2—*D. E. MacIntyre and J. L Gordon* 337
Human breast cancer responsive to androgen in long term tissue culture—*M. E. Lippman, G. Bolan and K. Huff* 339
Nerve growth factor-induced process formation by cultured rat pheochromocytoma cells—*A. S. Tischler and L. A. Greene* 341
Quantitative evaluation of concanavalin A receptor site distributions on the surfaces of specific populations of embryonic cells—*A. Neri, M. Roberson, D. T. Connolly and S. B. Oppenheimer* 342

[illegible]

Guide to authors

Articles are up to 3,000 words in length with at most six displayed items (figures and tables) and may either be reports of major research developments in a subject or broader reviews of progress.

● Letters are brief reports of research of unusual and wide interest, not in general longer than 1,000 words; at most they have three or four displayed items (figures and tables).

● 'Matters Arising' permits occasional short discussion of papers that have previously appeared in *Nature*. There is a limit of 300 words.

Manuscripts may be submitted either to London or Washington. Three typed copies should be submitted, each including lettered copies of figures. Typing (including references) should be double spaced. The title should be brief and informative. Pages should be numbered. References, tables and figure legends should start on separate pages. Experimental detail vital to the paper yet which would interrupt the narrative is best placed in the figure legends. Units should conform to the Système International. Greek characters should be identified in the margin on their first appearance. Equations should occupy single lines if possible, exp (a) is preferred to e^a if 'a' is more than one character. Articles should be accompanied by an abstract of not more than fifty words listing the main conclusions.

References are indicated by superscripts in the text. See any contemporary *Nature* for style, but note:

(i) To refer to several references by the same author at once, only one reference number need be given.

(ii) Cite first and last pages.

Abbreviations should follow the *World List of Scientific Periodicals*, fourth ed. (Butterworth, 1963-65). Symposia are often difficult to refer to and only published or soon-to-be-published volumes should be mentioned in references. Their publisher and place of publication should be clearly indicated. 'Personal communication' and 'unpublished work' should be incorporated in the text.

Artwork should be sent with the manuscript. All artwork should be marked with the author's name. Line drawings should preferably be in Indian ink on heavy cartridge paper, although other materials are acceptable: thin, shiny, folded, torn or heavily handled material should be avoided. Matt rather than glossy photographs are preferred. Figures are usually reduced to one column width. The originals should be about as wide as a page of *Nature*. Figures, particularly maps, should contain nothing but essential material. It is preferred that the original be unlabelled, but with a copy containing lettering. Labelling on photographs should if possible be avoided entirely. We are always glad to see artwork for possible use on the cover, whether or not it is associated with a manuscript, but cannot guarantee the return of material.

In order to save on postal expenses we return only the top copy and artwork of manuscripts that we cannot publish.

A fuller guide appeared in *Nature* (**246**, 238; 1973).

Redistribution of surface-bound polyelectrolytes on erythrocytes—*B. Larsen* 344

Erythrocyte morphology and clustering of fluorescent anti-A immunoglobulin—*J. A. Gordon and M. D. Marquardt* 346

Accumulation of 1,2-diacylglycerol in the plasma membrane may lead to echinocyte transformation of erythrocytes—*D. Allan and R. H. Michell* 348

Autoradiographic localisation of α-bungarotoxin-binding sites in the central nervous system—*G. Polz-Tejera, J. Schmidt and H. J. Karten* 349

Slowing of ionic currents in the voltage-clamped squid axon by helium pressure—*J. V. Henderson, Jr and D. L. Gilbert* 351

Role of PEP carboxylase during seed development in *Pisum sativum*—*C. L. Hedley, D. M. Harvey and R. J. Keely* 352

Inactive complex formation between *E. coli* RNA polymerase and inhibitor protein purified from T7 phage infected cells—*B. A. Hesselbach and D. Nakada* 354

Yeast mitochondrial RNA contains a short polyadenylic acid segment—*F. J. Hendler, G. Padmanaban, J. Patzer, R. Ryan and M. Rabinowitz* 357

Mutation rate, genome size and their relation to the rec concept—*J. A. Heddle and K. Athanasiou* 359

Stimulation of mouse lymphocytes by insoluble anti-mouse immunoglobulin—*D. C. Parker* 361

Identical sequence of light chains from rabbit anti-streptococcal antibodies—*D. G. Braun, H. Huser and J-C. Jaton* 363

Syntheses and immunological evaluation of bovine proinsulin C-peptide analogues—*N. Yanaihara, N. Sakura, C. Yanaihara, T. Hashimoto, A. H. Rubenstein and D. F. Steiner* 365

Erratum 366

Guide to authors

- Articles are up to 3,000 words in length with at most six displayed items (figures and tables) and may either be reports of major research developments in a subject or broader reviews of progress.
- Letters are brief reports of research of unusual and wide interest, not in general longer than 1,000 words; at most they have three or four displayed items (figures and tables).
- 'Matters Arising' permits occasional short discussion of papers that have previously appeared in *Nature*. There is a limit of 300 words.

Manuscripts may be submitted either to London or Washington. Three typed copies should be submitted, each including lettered copies of figures. Typing (including references) should be double spaced. The title should be brief and informative. Pages should be numbered. References, tables and figure legends should start on separate pages. Experimental detail vital to the paper yet which would interrupt the narrative is best placed in the figure legends. Units should conform to the Système International. Greek characters should be identified in the margin on their first appearance. Equations should occupy single lines if possible, exp (a) is preferred to e^a if 'a' is more than one character. Articles should be accompanied by an abstract of not more than fifty words listing the main conclusions.

References are indicated by superscripts in the text. See any contemporary *Nature* for style, but note:

(i) To refer to several references by the same author at once, only one reference number need be given.

(ii) Cite first and last pages.

Abbreviations should follow the *World List of Scientific Periodicals*, fourth ed. (Butterworth, 1963-65). Symposia are often difficult to refer to and only published or soon-to-be-published volumes should be mentioned in references. Their publisher and place of publication should be clearly indicated. 'Personal communication' and 'unpublished work' should be incorporated in the text.

Artwork should be sent with the manuscript. All artwork should be marked with the author's name. Line drawings should preferably be in Indian ink on heavy cartridge paper, although other materials are acceptable: thin, shiny, folded, torn or heavily handled material should be avoided. Matt rather than glossy photographs are preferred. Figures are usually reduced to one column width.
The originals should be about as wide as a page of *Nature* Figures, particularly maps, should contain nothing but essential material It is preferred that the original be unlabelled, but with a copy containing lettering. Labelling on photographs should if possible be avoided entirely. We are always glad to see artwork for possible use on the cover, whether or not it is associated with a manuscript, but cannot guarantee the return of material.

In order to save on postal expenses we return only the top copy and artwork of manuscripts that we cannot publish.

A fuller guide appeared in *Nature* (**246**, 238; 1973).

Possible biochemical explanation for specific reformation of synapses between muscle and regenerating motoneurones in cockroach—*J. L. Denburg* 535

Corrigendum 774

Guide to authors

- Articles are up to 3,000 words in length with at most six displayed items (figures and tables) and may either be reports of major research developments in a subject or broader reviews of progress.
- Letters are brief reports of research of unusual and wide interest, not in general longer than 1,000 words; at most they have three or four displayed items (figures and tables).
- 'Matters Arising' permits occasional short discussion of papers that have previously appeared in *Nature*. There is a limit of 300 words.

Manuscripts may be submitted either to London or Washington. Three typed copies should be submitted, each including lettered copies of figures. Typing (including references) should be double spaced. The title should be brief and informative. Pages should be numbered. References, tables and figure legends should start on separate pages. Experimental detail vital to the paper yet which would interrupt the narrative is best placed in the figure legends. Units should conform to the Système International. Greek characters should be identified in the margin on their first appearance. Equations should occupy single lines if possible, exp (a) is preferred to e^a if 'a' is more than one character. Articles should be accompanied by an abstract of not more than fifty words listing the main conclusions.

References are indicated by superscripts in the text. See any contemporary *Nature* for style, but note:

(i) To refer to several references by the same author at once, only one reference number need be given.

(ii) Cite first and last pages.

Abbreviations should follow the *World List of Scientific Periodicals*, fourth ed. (Butterworth, 1963-65). Symposia are often difficult to refer to and only published or soon-to-be-published volumes should be mentioned in references. Their publisher and place of publication should be clearly indicated. 'Personal communication' and 'unpublished work' should be incorporated in the text.

Artwork should be sent with the manuscript. All artwork should be marked with the author's name. Line drawings should preferably be in Indian ink on heavy cartridge paper, although other materials are acceptable: thin, shiny, folded, torn or heavily handled material should be avoided. Matt rather than glossy photographs are preferred. Figures are usually reduced to one column width. The originals should be about as wide as a page of *Nature*. Figures, particularly maps, should contain nothing but essential material. It is preferred that the original be unlabelled, but with a copy containing lettering. Labelling on photographs should if possible be avoided entirely. We are always glad to see artwork for possible use on the cover, whether or not it is associated with a manuscript, but cannot guarantee the return of material.

In order to save on postal expenses we return only the top copy and artwork of manuscripts that we cannot publish.

A fuller guide appeared in *Nature* (**246**, 238; 1973).

The Zoological Record

YOU NEED A KEEN EYE
for literature searching today

The **ZOOLOGICAL RECORD** can provide you with quick and easy access to the masses of papers being published in zoology enabling you to

- *trace all recent publications on a particular subject*
- *compile a complete record of an author's work*
- *assemble a comprehensive bibliography for any given topic*
- *spend less time on literature searching and more time on other activities*

The **ZOOLOGICAL RECORD** is the world's largest and most comprehensive bibliography in zoology

For further details contact

Do scientific journals need a code of practice?

THE Scientific Information Committee of the Royal Society has recently put forward a set of guidelines for the refereeing of papers for publication. The status of the guidelines is unclear in the context in which they have been presented (as part of the programme for a conference of editors), but it seems that for the present they are open for discussion, and that even after such discussion they will only represent an informal set of rules to which editors may or may not choose to conform. We believe that such a voluntary code of practice is unworkable, will cause more trouble than it is worth and should be quietly dropped.

The committee is right in one respect: there is a growing feeling that the processes by which scientists regulate each other's activities, be it through grant-giving, refereeing and editing, or even control of membership of learned societies, could with profit be made somewhat more open. There are still, we think, strong objections to a system in which all is revealed and the names of referees and advisers are made public. But there are obvious intermediate positions in which the supplicant at least knows what sort of treatment to expect and can thus choose his own strategy accordingly. Unfortunately the issuing of guidelines suggests a move to uniformity, whereas what is actually needed is a preservation of diversity to allow individual scientists in individual cases to make individual choices.

Furthermore, once a set of guidelines is published there will be a tendency for some aggrieved authors to look to the guidelines for redress, even if the journal has never claimed to conform to them.

In matters of dispute it is clear that the drafting of the document leaves much to be desired, as loopholes abound. Three of the guidelines with which we disagree strongly are:

- Every paper submitted to a journal for publication should be refereed.
- No paper should be rejected on the adverse report of a single referee.
- A definite procedure should be established for editorial decision within a stated period.

However worthy these statements are, they are unworkable—indeed undesirable—in particular instances; and it is often in these very instances (admittedly rare) that the author is looking for a way to prolong the battle. What is one to do about the author who scatters his paper with unsubstantiated statements, demands that not one but two referees should see it and insists that the journal should decide within a stated period? Supporters of the guidelines say that this is where editorial discretion comes in and of course "every" doesn't mean "every". But this leaves us with an additional guideline—'the editor may choose to ignore these guidelines'. From a straw poll it is clear that many editors by no means conform and have no intention of doing so. It will surely bring the guidelines into discredit if they are widely ignored.

An alternative response to calls for more openness should be considered. If journals were to state regularly what their policy was in handling manuscripts, and the extent to which editorial discretion entered, prospective authors would actually have a clearer impression of how they stood.

With this in mind we have compiled the following brief statement of our editorial procedures.

Nature aims to publish scientific reports which are suited to a wider readership than a specialised journal can provide; manuscripts concerned with any branch of science will be considered. The spectrum of papers published broadly represents that of papers submitted.

All papers are assessed by one of the three manuscript editors (two, a biologist and a physical scientist, based in London; one, a biologist, based in Washington). These three editors may consult with other editorial staff and will return roughly a quarter of all manuscripts at an early stage, chiefly on the basis that they do not have any obvious broad appeal. The remainder are sent to one referee (occasionally two) and the referee's recommendation is generally followed. On rare occasions a negative report is overruled when there seems to be a pressing need for a particular paper to be made widely and rapidly available. Somewhat more often a paper that has received only a lukewarm recommendation from a referee is declined for reasons of limited space. Specific comments from a referee are usually passed on to authors.

The objective is to make a decision in principle on papers within a month of receipt, although authors are often asked at that stage to revise or shorten manuscripts. The present acceptance rate for submissions to *Nature* is around 35%, and following acceptance we aim to publish papers within six weeks.

We propose to publish an updated version annually.

Victory celebrations in Hanoi: pace of scientific organisation quickens

Vietnamese journey

Any country aspiring to an industrial and technological competence must have an underlying strength in basic science. The North Vietnamese know this, and taking their characteristic long view, have been organising their war-depleted scientific cadres into a versatile research nucleus. Their effort proceeded all through the war at whatever pace was possible, but wholesale evacuation of educational and research institutes to the countryside prevented rapid progress. As American participation in the war diminished and then ceased altogether, the pace of Vietnamese scientific organisation quickened. In June 1975, a scant six weeks after the formal end of hostilities, there were already strong indications that the Vietnamese will soon have high competence in the basic physical and biological sciences, as well as in the related applied fields of engineering, medicine and agriculture.—Arthur W. Galston reports.

AS a representative of the Scientists' Institute for Public Information (SIPI) and carrying a gift of books, chemicals and equipment from the Society for Social Responsibility in Science, I had been invited for a return visit to North Vietnam in June 1975. My first visit, made in April 1971 together with Ethan Signer of MIT, had led to interviews with Prime Minister Pham Van Dong, the Ministers of Higher Education, Public Health, and Culture, and visits to numerous scientific institutions. Now in a Vietnam freshly at peace, I had been invited to lecture in my speciality, plant physiology and biochemistry, to instruct young scientists in techniques of plant cell and tissue culture, and to initiate a scientific aid programme from the United States (through SIPI) to the new Vietnam.

About four miles north-west of Hanoi, a large, modern science research centre is nearing completion. Financed by the USSR and constructed under Soviet supervision with Vietnamese labour, the centre was originally planned and administered by the State Committee on Science and Technology, the leading scientific policy making group in Vietnam. Since the end of the war, and to insure rapid progress, the centre, under its newly appointed director, Nguyen an Hieu, has been placed directly under Prime Minister Pham Van Dong, to whom Hieu reports directly. At a private conference with these two men, I was struck by their close rapport, and by the Prime Minister's understanding of and direct concern with scientific matters. Almost unconsciously, I had to contrast this with the situation in the United States, where in spite of its vastly greater competence and importance, American science has had no science adviser close to the President since Richard Nixon dismantled the structure that had been created and successively strengthened by his five predecessors.

Hieu is a 39-year-old theoretical physicist who received his training under the noted Professor Bogolyubov at Dubna, the huge research centre near Moscow run by a consortium of Warsaw Pact nations. In addition to his role as director of the centre, Hieu directs the Institute of Physics, one of the six operating units of the centre. Since the completion of his PhD training in 1961, Hieu has made substantial contributions to the field of elementary particle theory, and now, as a member of the governing council at Dubna, visits that establishment every year. Five of his students have also received their basic training at Dubna, and in recognition of this growing Vietnamese competence in physics, the Dubna consortium recently donated advanced research equipment worth, conservatively, half a million dollars to the centre. This equipment is now largely set up and functioning in a series of huts and basement rooms of the centre, but with the imminent completion of that structure, will move into more spacious, even elegant, quarters.

Aware of the potential practical importance of research in solid state physics, Hieu has recently shifted to that field, and the laboratory's organisation reflects that emphasis. Already, large germanium and bismith-tellurium single crystals have been grown, their impurities removed in a diffusion separation furnace, and the resulting purer crystals thinly sectioned to furnish the elements of semiconductor diodes for amplifiers. Sprinkled around the laboratory is a mixture of advanced equipment from many nations in the Soviet bloc, as well as the latest in scientific publications from all over the world, efficiently and cheaply reproduced by the Chinese without royalty payments. I saw a large Soviet neutron generator in the activation analysis of minerals and proteins, several multichannel data analysers from East Germany, a computer of Hungarian design based on American integrated circuits, and an advanced spectroscopy laboratory with many components from France, Great Britain and West Germany. A large X-ray laboratory is involved in analysing the structure of crystals and a solar energy group is using semiconductors to translate light energy directly into usable quantities of electricity. These activities would be thoroughly familiar to western physicists, and it is clear that besides playing a role in the development of science in their own country, Vietnamese physicists are eager to enlarge their contacts with the rest of the world.

I could get no exact figures on the cost of the Science Research Centre but I judge its approximate area at

500,000 square feet of usable space. At even $20 a square foot, a ridiculously low level by western standards, the building alone will be worth $10 millions when completed. Together with its abundant scientific equipment, it should eventually be worth about $25 million. Though not especially impressive by American standards, this is enough to make it one of the largest installations in Vietnam. In the North, it will probably be second only to the $75 millions paper mill being donated and built by the Swedes under an official aid programme.

In addition to the Institute of Physics, the centre will house the Institute of Mathematics, founded in 1969 under Le Van Thiem, a German-trained PhD. The still embryonic institutes of biology, earth sciences and oceanography are as yet still without directors. A chemistry laboratory devoted to the study of catalysis will serve as a nucleus for the ultimate development of an Institute of Chemistry, for which the Vietnamese judge they do not yet have sufficient competent personnel. A computer centre will complete the presently contemplated facilities.

I was, in fact, the first visiting foreign scientist in what Hieu envisions as an expanding programme central to the intellectual life of the centre. My lectures on plant physiology and biochemistry were attended mainly by those biologists close to that area, but I was impressed with the fact that physicists attended when I spoke on effects of light on plants, and both animal and microbial biochemists attended when I talked on the biochemistry of plant growth hormones.

I instructed a small research group in some new biological techniques and found the young scientists well trained in basic concepts and eager to learn, though several years out of date. They were proud to be the occupants of the first three finished rooms in the entire centre. These had been completed much before schedule in connection with plans for my visit, and the Soviet engineer and architect came around during one working day to ask whether I found everything satisfactory. That struck me as meaningful *detente* in action.

Though the centre is the most competent of the research facilities in North Vietnam, it is certainly not the only one. Much work in strength of materials goes on at the Hanoi Polytechnic Institute, in vaccines at the National Institute of Hygiene and Epidemiology, in liver cancer at the Viet Duc Hospital, in natural plant products and pharmaceuticals at several institutes, and in agronomy and herbicides at the Agricultural University. By contrast, the University of Hanoi has pitifully few laboratories for modern research, despite its major educational role. The biologists there listened with obvious envy as the American programme of aid to the Science Research Centre was outlined. Couldn't we help them too, they wanted to know. But they understood that our present limited resources would make no impact at all if too widely disseminated. They felt somewhat better when I promised to seek specific aid for them from other American sources.

Though scientific groups were understandably eager to receive American aid, official or unofficial, there was general agreement that American scientists have a special responsibility to continue investigations on the yet largely unknown consequences of the massive military defoliation operations in the South. In the decade starting about 1971, we dropped from aeroplanes about one hundred million pounds of chemicals toxic to plants over an area of South Vietnam greater than that of the state of Connecticut. About a quarter of South Vietnam's dense upland forests, one-third of its coastal mangroves, and perhaps one-tenth of its agricultural lands, were sprayed in an attempt to deprive the guerillas of forest cover and food resources. In spite of several Department of Defense-sponsored studies by US scientists, the ultimate ecological effects of this massive operation are not yet known, but several immediate effects, especially in the mangroves, are known to be severe.

Perhaps more important is the danger to public health, for it is now known that one of the herbicides used, 2.4.5-T. contained significant quantities of an impurity called TCDD (2,3,7,8-tetrachlorodibenzodioxin). Very small quantities of this material, in the parts per thousand million range, can cause death, the malformation of developing embryos in laboratory rats and mice, and chromosomal aberrations in dividing plant and animal cells. The latter observation raises the possibility that TCDD can also cause mutations and cancer. Dr Ton That Tang is suspicious that the recent marked upsurge in liver cancer all over Vietnam may be related to TCDD persistence in the soils of sprayed areas. If this chemical were slowly released into streams, it would find its way into the algae and fish of the ocean, and ultimately into the human diet. Furthermore, since the ocean currents carry waters from south to north, Tung feels that TCDD sprayed in the South could affect civilians in the North. All this evidence is circumstantial, but since TCDD was detected in fish collected in 1973, two years after the herbicide spraying programme had been terminated, and since its persistence in soil and water is not known with certainty, the possibility of contained danger to public health and ecosystems continues.

Can the US turn its back on this problem? Or does American responsibility for investigation continue? Whether or not the US ever decides to give official scientific aid to Vietnam, many feel that it has a moral obligation to follow through on this research, much as it did after dropping an atomic bomb on Hiroshima.

Ta Quang Buu, a dynamic, Cambridge-educated mathematician, has served as Minister of Higher Education in North Vietnam since 1965. When I first met him in Hanoi in 1971, he impressed me with his keen, driving intelligence and his energetic devotion to the ideal of the best posible educational system for his country's youth, even in the midst of a debilitating war. But like many officials in the new Vietnam, Ta Quang Buu is finding the problems of peace more formidable than the problems of war.

Consider some of the difficulties facing him. One quarter of North Vietnam's population of almost 25 million is now at school. The figures for the South are not yet precisely known, but they are assumed to be rather similar. For the past 20 years, North and South have gone their separate educational

Plant physiologists at a Galston lecture

ways; their aspirations, philosophies of education and methodologies have been as different as communist and capitalist orientations can make them. Can two such systems possibly be unified? Should they be? If so, should change be gradual or sudden? What good points in the southern educational system can be adapted to the North? How should one handle the problems of adult education, given the imminent demobilisation of hundreds of thousands of soldiers? Although the end of the war came with dramatic suddenness, Buu's deputies have already travelled to the South for liaison with their counterparts. As staggering as the problems seem to be, Buu and his colleagues are tackling them with the same stubborn determination that characterised Vietnam's long military struggle.

In considering how best to mobilise and unify the educational and scientific resources of the North and South, Buu has analysed the situation in the South. Before 1973, he told me, university education in the South was completely dominated by the French model. The outstanding characteristics of this model are, first, an emphasis on general education, with only scant technical or vocational training being offered; second, the complete autonomy of the various faculties in devising standards, curricula and entrance requirements; third, no selective examinations at entrance, but rather massive elimination of students along the way (recently 60% have been eliminated after the first year and between 75 and 90% have never graduated); fourth, no assurance of a job after graduation and thus no limitation on the number of students choosing an option.

This unplanned system has resulted in an asymmetric and, according to Buu, chaotic expansion of the student population in southern universities. They now number more than 120 000, and of these, fully 50,000 are studying literature and law, preparatory to a legal career. "What can we do with so many lawyers?", exclaims Buu. "Ways will have to be found to alter the course of their studies, to divert them to other occupations". In similar fashion, the many students in training for financial careers will be retrained "to make good clerks and civil servants for the new system", and some of the many potential secondary school teachers will be encouraged to seek other occupations.

By contrast, the North Vietnamese system emphasises educational quotas in the various specialities as part of the planning for the filling of anticipated job vacancies. It also includes stiff, competitive entrance examinations, minimum dropouts along the way, and limited autonomy of the individual faculties under a more centralised and highly codified system of national education. Following this system, which Buu believes resembles the American more than the French, the North Vietnamese have admitted only 55,000 students to higher educational institutions. This represents a decline from the 70,000 students enrolled in 1973, caused by the raising of educational standards. Obviously, to integrate the northern and southern educational systems, some compromises must be made in standards for admission and dropout projections, as well as in educational objectives and practices.

Paradoxically, American educational innovations introduced into the South about 1973 have shaped the system more toward the northern model. For example, the introduction of two-year community colleges at Da Nang, Nha Trang, Tu Duc and several other locations accords well with plans in the North to reserve the established universities for the final year of more specialised training. Also, under American guidance, polytechnic institutes were established for the training of engineers and other specialists. This too fits in well with the North Vietnamese approach. Hanoi Polytechnic Institute, built during the war, with Russian aid, would seem familiar in basic organisation to a student at MIT or Caltech. With typical Vietnamese eclecticism, Buu proposes to combine the best aspects of these various systems into a new, indigenous approach. "Bilateral accommodation" and "smooth interpenetration" were some of the phrases he used to describe how the process might work.

Even before the final formula has been devised, educational institutions closed by the war have been reopened. For example, Hue University was back in operation by April 14, and the Medical and Pharmacy faculties in Saigon reopened in June, barely a month after the end of the war. Though a few teachers fled with the departing South Vietnamese officials, almost all, according to Buu, are fitting in well with the new system, and are actively seeking guidance in making the accommodation. This is especially important since the student body, previously limited to the privileged classes, will now include many peasants and workers, for whom new educational techniques will have to be introduced.

Buu believes that equality of educational opportunity has already been widely implemented in the North, through improvement of rural secondary schools, through extensive adult education programmes, and by giving preference in university admissions to those with some work or military service experience. This year, approximately 35–40% of the 10,000 students to be admitted to universities in the North will have such work experience. Since there will be about 80,000 applications in all, this will give a substantial competitive advantages to the more experienced applicants. Yet, Buu is all for flexibility, and definitely rejects the Chinese model of requiring work experience before admission to the university. Especially gifted or critically needed students should not, he feels, be held to that requirement.

There are as yet no postgraduate training centres in Vietnam for work leading to the PhD or equivalent degree. During the war, it was the practice to send promising students abroad, especially to the Socialist countries of eastern Europe, for such training. In 1969, there were about 12,000 such students abroad; the number is now down to about 7,000 and Buu expects it to go even lower as centres for such training develop in the time when some promising candidates can be sent to western Europe Vietnam. But he also looks forward to and even the United States, especially for training in science and technology.

Can the United States play a role in the postwar educational reconstruction of Vietnam? Like Prime Minister Pham Van Dong, noted surgeon Ton That Tung and other officials I interviewed, Buu insists that the Vietnamese do not hate, and in fact in many ways admire Americans. Under proper conditions, he would be glad to receive American aid. Gifts of books and scientific equipment, lectures and seminars by visiting specialists and exchange by communication are possible and desirable immediately. Exchanges of teachers and students are not desirable or possible now, but may be within two or three years, after the reunification of North and South has been accomplished, and their major educational patterns have been firmly charted.

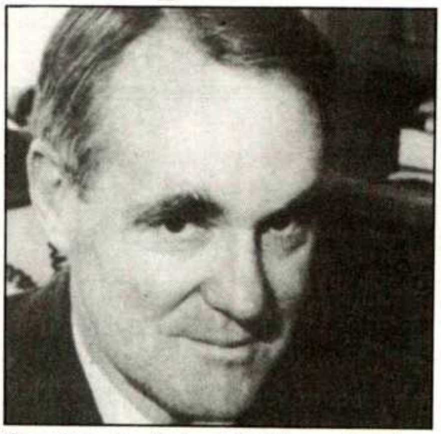
Since American science and technology has been so extensively used for destructive purposes all over Vietnam, Buu believes it would be uniquely appropriate for groups of scientists to lend their talents to the reconstruction efforts now under way. In the light of President Ford's and Henry Kissinger's stated opposition to any such official aid, assistance would have to be unofficial and "people to people". The joint project of the Scientists' Institute for Public Information and the Society for Social Responsibility in Science was, he felt, an appropriate model. But he is neither doctrinaire nor proud in this matter. He will accept any appropriate aid given in good faith, confident that the future will bring a normalisation of relations between his country and the United States. "Then", he says, his eyes lighting up, "the vast wealth and power of the United States can really be focused on the job of rebuilding our underdeveloped and battered country". ●

Cornforth's prize

J. W. CORNFORTH, who shares this year's Nobel Prize in Chemistry with V. Prelog, is now taking up, at the age of 58, a new full-time appointment as Royal Society Research Professor in the Department of Applied Science in the University of Sussex. He began his distinguished career in organic chemical research in Australia: he graduated at the University of Sydney and was awarded the University Medal in Organic Chemistry. This was followed by an 1851 Exhibition Overseas Scholarship to the UK, which he held from 1939 to 1942 in the Dyson Perrins Laboratory at Oxford with Robert Robinson, and he has remained in the UK since.

His early work was on Australian plant materials (with J. C. Earl) and he moved in Robinson's laboratory naturally. Inevitably in that environment he was attracted to the problem of the laboratory synthesis of cholesterol, and when the Second World War extended his stay in the UK, he was drawn into the maelstrom of the penicillin problem. In 1946 he joined the staff of the Medical Research Council at the National Institute for Medical Research and a career of individual work began to take shape; a summary is almost impossible to make: it would be a task of selecting highlights in a dazzling array of subjects. Enquiry into natural products, laboratory synthetical methods, fundamental reactions of biosynthesis, isotope techniques, reactions applicable to manufacture of medicinal products—all were grist to his mill; one has only to start discussion of a structural or synthetic problem with him to provoke a flow of 'graphite and cellulose' solutions. The only drawback to consultation is his complete deafness, which makes the problem of getting a word in edgeways and saying "yes, but" or "I thought of that" a difficult one. The handicap of deafness he has overcome magnificently, particularly with the aid of his wife, Rita, who is herself an organic chemist of great skill.

Cornforth's relation with Robert Robinson is best put in his own words.



Opening the Robert Robinson Lecture he gave to the Chemical Society in 1972 he said: "Our friendship . . . for more than 30 years has been a continuous sequence of differences of opinion". Reorientation of Cornforth's work, after the publication of some papers on miscellaneous subjects from the National Institute for Medical Research, came about in two ways in 1950. First, as a consequence of the Medical Research Council taking the lead in this country in the search for a source from which cortisone could be manufactured, and its involvement with the National Research Development Corporation, the workers at the National Institute were mobilised. Hecogenin, the steroid sapogenin from sisal (*Agave sisalana*) was found to be such a raw material, which, on the basis of fundamental chemical work at Mill Hill and development in collaboration with the staff of Glaxo Laboratories became of considerable commercial importance.

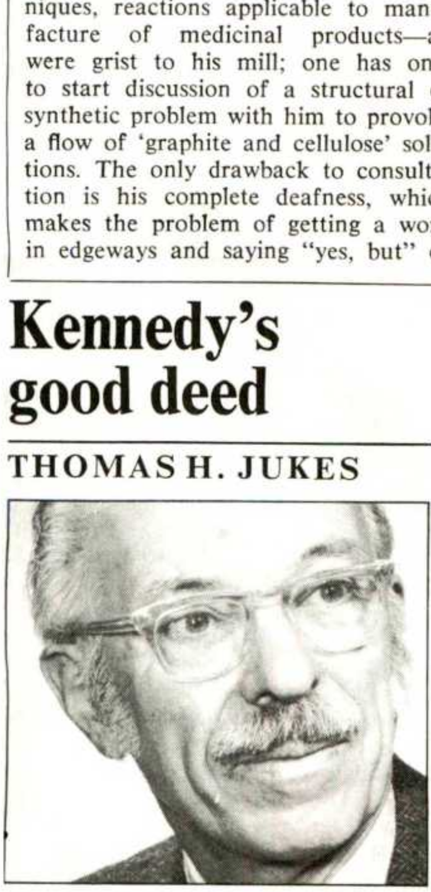
The second direction of development of Cornforth's work came in the early 1950s in association with George Popják, then in the Biochemistry Division at Mill Hill and later at the Medical Research Council's Radiopathology Research Unit. This work, which led, finally, to the results of fundamental theoretical significance for enzymology that have earned the Nobel Award, began with the examination of the problem of the route of biosynthesis of squalene from mevalonic acid. Development of new techniques for using isotopically labelled compounds, with such incidental ingenuities as the characterisation and orientation of the three hydrogen atoms of a methyl group by labelling with protium, tritium and deuterium followed, along with the extension to the study of enzyme stereochemistry on a wider basis.

In 1962, Cornforth and Popják became joint directors of the Shell Research Milstead Laboratory of Chemical Enzymology at Sittingbourne, an establishment that in the best tradition of schoolboy humour was dubbed at its inauguration the "Pop-Corn Laboratory". Unhappily Popják broke the link when he migrated to the USA. No doubt Cornforth's new laboratory in the University of Sussex will acquire some title of affection appropriate to the unique individuality of its presiding genius and certainly occupy an important place among the world's centres of scientific research.

R. K. Callow

Kennedy's good deed

THOMAS H. JUKES



ON September 8, the US Senate passed, by 61 votes to 29, a bill (S-963) introduced by Senator Kennedy to ban the use of diethylstilboestrol (DES) in growing beef cattle. The same bill would authorise the use of DES as a contraceptive after sexual intercourse only in rape, incest or "a comparable medical emergency" (the 'morning-after pill').

The bill carefully provides that the ban for beef must first be approved by the National Cancer Institute. This will be easy. Scientists of the National Cancer Institute have already testified before congressional hearings that one molecule of DES may cause cancer. Quite a lot of cancer cases were thus implied in a world population of 3×10^9 which is presumably exposed to molecular levels of DES in the air and water. One morning-after pill contains 7×10^{19} molecules.

Diethylstilboestrol is a known human carcinogen. Even worse, it is synthetic and man-made; a self-inflicted wound. Herbst, who discovered its carcinogenicity in human subjects, has calculated its cancer-causing potency: less than 4 cases per 1,000 in the female progeny of pregnant women receiving 1.5 mg (3×10^{18} molecules) of DES per day. He also notes that "there has been no documented correlation of maternal DES therapy with the development of cancer in males". Incidentally, DES is widely used as an anti-cancer drug in prostatic cases.

The intake of DES per capita from beef may be calculated from data for the residues found in implanted cattle, and the consumption of beef liver, 0.7 kg a year (0.12 parts per 10^9), plus beef muscle meats, 52 kg a year (0.012

parts per 10^9), in the USA. The intake corresponds to a daily dose of 1.9 ng, which is about 1.3×10^{-6} of the 1.5 mg used in Herbst's calculations. On a linear basis, the cancer risk to female offspring is, therefore, less than 5 cases per 10^9, corresponding to less than one case per 133 years in the 1.5 million females born annually in the USA. How much less than one case?

Probably quite a bit, but actually unmeasurable in view of the fact that other oestrogens predominate over this level the efficiency of conversion of feed into DES. Nubile women secrete oestrogenic potency equivalent to 300,000 ng of DES daily, and wheat germ contains oestrogens, measured by ingestion, equivalent to about 400 ng of DES per gram. Also, DES in beef liver is said to be present as glucuronide, which is inactive. The organic food crowd will applaud Senator Kennedy. More important, they will vote for him. Consumers will pick up the tab for the extra cost of beef production occasioned by the ban, which will decrease the efficiency of conversion of feed into lean meat by about 10%. Food prices are increasing so rapidly that this extra cost of up to $900 million will be lost in the spiral.

Of course the money might have been used for cancer prevention and treatment . . . But who wants to take a chance on getting cancer, even one case in 133 years in 200 million people of a form of cancer that responds to treatment?

Banning DES will call for about 7 million tons of corn to maintain the US beef production at its present level. Senator Kennedy has professed sympathy for the plight of starving people in Bangladesh. Seven million tons is a lot of corn. But sympathy has to make sense. These people don't vote in Massachusetts!

international news

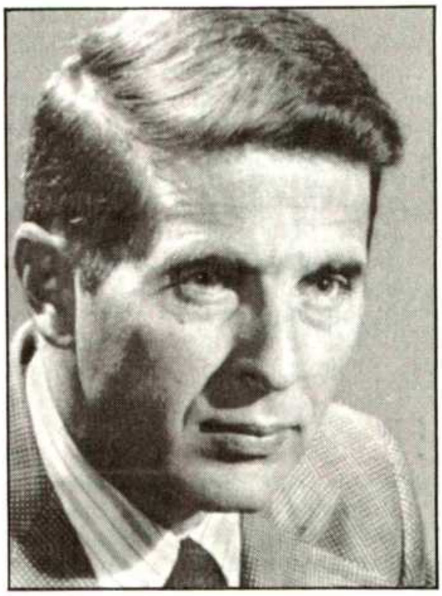
Computing the chances of a nuclear accident

by Colin Norman, Washington

FOR years, spokesmen for the nuclear industry and the federal government have been assuring the American public that the risks associated with nuclear power plants are vanishingly small. The nuclear industry has a safety record unblemished by any accident which has released radioactivity into the environment, the argument goes, and nuclear power plants are bristling with so many safety devices that the chance of something going calamitously wrong is close to negligible.

But, as five years of raging debate have amply demonstrated, those bland assurances have not convinced everybody. So, in August 1972, the Atomic Energy Commission decided—though with some doubts about the feasibility of the project—to launch a mammoth computer analysis of the probability that a nuclear reactor could go haywire and endanger the lives of people nearby. The final results of the analysis, which were made public last week, support the official assurances. Nevertheless, they are unlikely to still the nuclear debate.

In general terms, the analysis suggests that there is a finite chance of a catastrophic nuclear accident, but the risk is miniscule when compared with other hazards such as fires, explosions, earthquakes, tornadoes or hurricanes. As William A. Anders, Chairman of the Nuclear Regulatory Commission (NRC)—which assumed responsibility for the project when the Atomic Energy Commission was dismantled earlier this year—suggested last week, the analysis "reinforces the commission's belief that a nuclear power plant designed, constructed and operated in accordance with NRC's comprehensive regulatory requirements provides protection to public health and safety and the environment".



William Anders: reassuring

Carried out under the direction of Professor Norman Rasmussen, a nuclear engineer at MIT, the study involved a technique, widely used in the defence and aerospace industries, known as "event tree analysis". In short, the technique attempts to predict the chances of failure of various components in a reactor and to assess the effects in terms of release of radioactivity, loss of lives and damage to property. The Rasmussen study explored thousands of potential sequences of failures in reaching its conclusions.

The final results, contained in a massive 12-volume report, conform closely to preliminary estimates published by Rasmussen in a draft report last year. Although the draft report attracted more than 1,800 pages of comment from various individuals and groups—much of it highly critical—the most significant change required in the analysis, according to Rasmussen, was a large increase in the estimate of the number of cases of cancer resulting from a massive release of radioactivity.

The study concentrated on the possibility of occurrence of a string of mishaps which would cause the core of a reactor to melt. Surprisingly, the analysis suggests that the chances of a core melt are about 1 in 20,000 per reactor year, which is rather higher than many previously quoted estimates (which have generally been put at about 1 in 10^6). But it suggests that the consequences of such an accident may not be catastrophic. "Contrary to commonly held belief that . . . core melting would surely result in severe accidents with large consequences", the report states, "the magnitude of the potential consequences of a core melt accident were found to have a wide range of values. The probability is high that the consequences would be modest".

The analysis suggests, in brief, that if a core melts, the pressure vessel which encloses it would not necessarily rupture and release large quantities of radioactivity into the atmosphere. The core would, however, eventually melt its way into the ground, but the study suggests that most of the radioactivity would be trapped in the soil. The most likely consequence of a core melt, the study predicts, would be less than one death and less than $1 million worth of damage to property outside the plant itself.

The worst possible case would involve a series of accidents leading to a core melt, followed by a massive explosion which ruptures the pressure vessel and releases large amounts of radioactive gases into the atmosphere, a steady wind blowing toward a populous area, and rain occurring at a critical time so that most of the radioactivity would be dumped on the population centre. The possibility of such a calamity would be about 1 in 10^9 per reactor year, the analysis suggests, but it would result in about 3,300 deaths and cause about $14,000 million worth of damage to property.

The results of the analysis are stated in many ingenious ways in the report, the most widely quoted of which is sure to be the statement that a person living near a reactor stands a 2,000 times greater chance of being killed by lightning than of being killed by a nuclear accident.

Rasmussen said last week that he has high confidence in the accuracy of the predictions, and he pointed out that the methods used in the analysis have been endorsed by many groups. He readily acknowledged, however, that the study has its limitations. It does not deal with the possibility of sabotage, for example, but Rasmussen said at a press conference that it would be difficult to cause a very severe catastrophe by sabotage because of the existence of safety devices to prevent large releases of radioactivity following a core melt.

The analysis, moreover, is limited exclusively to an accident at an operating reactor, and does not include an assessment of the risks associated with waste disposal, the potential theft of atomic bomb ingredients by terrorist organisations, or other frequently cited hazards of nuclear power. The focus of the anti-nuclear power movement has recently shifted to those areas.

Needless to say, Rasmussen's conclusions have not met with widespread endorsement from groups which have been critical of the nuclear power programme in the past. Dr Arthur Tamplin, a scientist on the staff of the Natural Resources Defense Council, last week suggested that the report has little application to the real world. "Those numbers are fine for an academic discussion in nuclear engineering departments", he said, but "the exercise has no reality". In particular, he questioned the study's predictions about what would happen after a core melt, suggesting that the behaviour of a mass of molten fuel is entirely unknown. Another critic was even as unchivalrous as to suggest that the report was a typical computer programmer's nightmare of "garbage in and garbage out".

Nevertheless, the study is the most ambitious attempt so far to place hard numbers on the official assertions that nuclear power is safe, and it will clearly form the basis of nuclear regulation in the United States for many years. Rasmussen warned, however, that the results of the analysis should not be extrapolated beyond the first 100 or so operating reactors in the United States. Later reactors, he suggested, will be even safer because of constant improvements in the safety systems.

As a footnote, it should be noted that the report could actually be seen as a boon for critics of nuclear power. At present, insurance against nuclear accidents is limited by law to a total of $560 million per accident. The law, known as the Price–Anderson Act, has been bitterly contested by nuclear critics, who argue that in the event of a nuclear accident, full compensation should be paid for health and property damage. If the dangers are really as remote as the Rasmussen analysis predicts, and the consequences likely to be small, then why should there be any limits to the liability? A statement published last week by the Friends of the Earth suggested that the Price-Anderson Act "points out the hypocrisy and inconsistency of the federal government's policy towards nuclear power". □

FOR the first time since 1969, the number of students enrolled in postgraduate science and engineering courses in the United States increased last year. According to a survey carried out by the National Science Foundation (NSF), the increase amounted to nearly 6% and the total number climbed back to the level of 1967.

Although the upturn makes a welcome change for many universities, which have been financially hard pressed and which have had to impose a virtual freeze on faculty recruitment partly because of declining enrolments in the early 1970s, the renewed interest in postgraduate education is of uncertain durability and it is concentrated heavily in a few fields.

The sharpest increase occurred in the life sciences, where the number of postgraduate students jumped by 11.3%. Psychology and the social sciences also showed substantial increases—8.0 and 6.6% respectively—while in engineering and the physical sciences there was only a slight upward trend. Engineering enrolments increased by 3.3% and those in the physical sciences by 1.4%; enrolment for the mathematical sciences declined a little.

The increases are surprising since they came at a time of continuing decline in direct government support of postgraduate students. The number of postgraduates receiving support from the federal government has declined by some 42% since 1967, and the trend shows little sign of abating because it is declared federal policy to phase out most graduate fellowship programmes. In contrast, the number of postgraduates supporting themselves through their studies is increasing—numbers were up by 14% between 1973 and 1974.

One explanation for the renewed interest in postgraduate education is that many scientists and engineers who received their first degrees in 1973 were faced with a tight job market, and elected to stay on at the universities to increase their chances of finding suitable employment. As far as enrolment in the life sciences is concerned, the sharp increase probably reflects the fact that there is at present a fashion in the United States for studying medicine—a year or so ago it was law—and many students who failed to get into medical schools turned to closely related fields in the life sciences.

Does the upswing in graduate enrolments indicate a return to the golden years of university expansion in the 1960s? Almost certainly not. The driving force for expansion a decade ago arose partly from large increases in federal support for science and technology and partly from the fact that the post-war baby boom was passing through the universities. The federal science budget is now virtually stagnant in terms of spending power, and demographic trends suggest that there will be little expansion of the college-age population for the next two decades.

One particularly interesting fact to emerge from the survey is that the number of women enrolled in postgraduate science and engineering courses has been increasing sharply during the past few years. Women represented 24% of all full-time graduate students last year, and their numbers had increased by 13% since 1973. They were concentrated chiefly in the life sciences and the social sciences. The survey also reflects the fact that government restrictions on the employment of foreign students is continuing to depress their numbers. There were 3% fewer foreign students enrolled in postgraduate science and engineering courses last year, and their representation in the total postgraduate population declined to 16%.

Brazil and biodegradable detergents

from Bruce Handler, Rio de Janeiro

THE Brazilian Congress is studying a proposal to ban the manufacture of non-biodegradable detergents in this country, which is slowly waking up to the problems of pollution. The bill, which orders detergent makers to produce only non-polluting products, has passed the House Constitution and Justice Committee. It still must win the approval of the entire House, the Senate and the President to become law, however. Observers in Brasilia say the chances are good, in view of other recent indications that Brazil is abandoning its one-time policy of development at any price in favour of one that shows more concern for protection of the environment.

The detergent bill came as a result of a recent invasion of foul-smelling white foam that drifted off the Tiete River in the south-eastern part of the country and literally covered the Sao Paulo suburb of Santana do Parnaiba. The tropical town looked as if it had been hit by a freak snowstorm. Environmental experts were unanimous in blaming excess amounts of non-biodegradable detergents that had been dumped into the river as the principal cause.

Concern over the Santana do Parnaiba incident was expressed as far away as Argentina, because the polluted Tiete empties into the Parana–Plate river basin. Because of Brazil's relative lack of concern about pollution until now, it may be prohibitively expensive to implement the detergent bill, even if it is passed quickly. Brazil at present imports all the benzine distillates needed to make biodegradable detergents, and because of a disastrous balance-of-payments situation caused by the high price of foreign crude oil, the government has ordered a drastic cutback on all but the most essential imports. The situation is even more pessimistic when one takes into account the fact that detergents are responsible for only a small percentage of water pollution in Brazil.

In August, President Ernesto Geisel signed a decree saying that all industries in Brazil must control pollution and giving the federal government the power summarily to close factories that foul the envinronment. This is quite a change from Brazil's position on pollution just a few years ago, when it told an international conference on the environment: "A country that has not yet reached satisfactory living standards cannot sidetrack its resources for pollution control."

The new decree does not mean, however, that this fast industrialising nation of 110 million people is going to become a paragon of environmental protection overnight. In fact, many pollution-conscious people here felt the immediate purpose of Geisel's decree was to stop state and local government from cracking down too hard and too fast on polluters, and thereby interfering with national development plans.

Cabinet ministers who suggested the anti-pollution measure to the president noted that although Brazil has an "acute" industrial pollution problem, the government must be careful "not to disorganise productive activities or cause social unrest" This seemed to be fancy wording for the problem of citizens in several Brazilian cities who have shown themselves to be at their wits' end because of pollution—and who would take to the streets in protest, if public demonstrations were not illegal under the military-controlled regime here.

A typical case occurred recently in the industrial town of Contagem outside Belo Horizonte, Brazil's third largest city. There, a cement factory whose smokestacks spew out over 100 tons of particles a day on local residents' houses had been promising for years to install pollution control equipment but never did. The people of Contagem complained that the factory was responsible not only for the white dust that covered everything in sight but also for widespread respiratory ailments.

Mayor Newton Cardoso finally ordered the factory closed. He said that "the human being must always be the focus of the government's attention." State police were sent out to make sure the plant's executives began shutting down production equipment, to comply with a deadline the mayor had set. In addition, the DOPS—the much-feared political police—went to the cement factory after hearing reports that townspeople were going to hold a demonstration there to celebrate Mayor Cardoso's decision.

Then the presidential decree came out. A judge rescinded the mayor's order, on the grounds that local authorities could no longer single-handedly shut down factories. The cement plant continues to operate, although its owners have promised to install anti-air pollution devices in 1976.

Paulo Nogueira Neto, who holds the recently created federal post of special secretary for the environment in Brazil, summed up the dilemma: "The important thing is not to pollute. But we also cannot ignore the economic side of the problem." He added that the new presidential decree "makes it clear that pollution control is obligatory and that there will be no loosening up."

Brazil has made remarkable economic progress since a development-minded but politically repressive government took power in 1964. But it has paid a high price in ecological terms.

Pollution in Sao Paulo, the nation's largest city, has become so bad that a leading department store now stocks anti-pollution masks—in adults' and children's sizes. Sao Paulo's last mayor won applause from the populace when he temporarily closed a polluting cement factory there. But this led to a political fight with the governor, and the mayor lost his job. The factory is open again, and the particle fallout is as bad as ever.

Local authorities in the southern state of Rio Grande do Sul succeeded in closing down a foul-smelling cellulose factory that had been built by a big Norwegian pulp and paper manufacturer. But that factory is now in business again. The Norwegians sold their share of the undertaking to private Brazilian interests, and an influential retired Army general was installed as president of the company.

Federal Representative Jose Roberto Faria Lima, a supporter of the bill to ban non-biodegradable detergents, made this comment: "It's too bad the Tiete River had to become covered with foam before the need was shown for a law requiring the production of biodegradable detergents in this country. Anti-pollution plans and even the President's decree don't do any good. Simply saying: 'It's against the law to pollute' doesn't stop pollution". □

Coal standard

from Vera Rich

DONETSK, in the Ukrainian SSR, has been accepted as the standard coalfield by the Eighth International Congress of Stratigraphic and Carboniferous Geology, which met recently in Moscow. The phenomena of the Donetsk field will be used as a basis for a unified international scale to be used in prospecting and establishing the boundaries of coal fields. The scale, which was proposed by a team of geologists from Britain, France, the USA and the Soviet Union, is at present at the draft stage. Nevertheless, the acceptance of Donetsk as the standard seems unlikely to be changed by further discussions, since this field is unique in giving a clear and detailed picture of the history of the whole of the Carboniferous period (345–280 Myr BP) Although Donetsk was selected on the basis of its geology, this coalfield has a history which may serve as a promising augury for international cooperation. As its original name of Uzhovka indicates, it was first opened up (1869–1870) by a Welsh mining expert by the name of Hughes. □

Letter from Israel

from Nechemia Meyers

AN idea first put forward by Zionist visionary Theodore Herzl 73 years ago, and then brought up again four decades later by an American soil conservationist, Walter Clay Lowdermilk, may soon, at long last, be implemented.

Herzl, Lowdermilk and others have advocated the construction of a canal (or tunnel) through which seawater would flow from the Mediterranean to the Dead Sea so that the difference in level of 400 m could be exploited for electricity generation.

Advocates came and went, but only recently, prompted by the energy crisis, did the government appoint a committee seriously to consider the possible implementation of such a scheme. The committee, headed by Bar-Ilan Professor Shlomo Eckstein, had before it a plan for building a 75-km tunnel which would bring Mediterranean water to a reservoir in the Judean Desert highlands overlooking the Dead Sea, from which it would be 'dropped' through turbines with an installed capacity of 300 MW.

The next stage, if the Eckstein committee's recommendations are accepted by the government, will be a 'prefeasibility study', including test drillings at various places along the proposed route.

According to present estimates, the project will require 10 years to complete and cost more than $200 million (at present prices). In operation, it will not only increase electricity supplies but also replenish the rapidly evaporating waters of the Dead Sea, from which large quantities of potash, bromine and other valuable minerals are extracted Traditional sources of replenishment, particularly the inflow from the Jordan River, have gradually dried up as more and more sweet water is being syphoned off upstream by Israelis and Jordanians for irrigation purposes.

There is, however, a limit to the amount of seawater that can be poured into the Dead Sea if it is not to overflow. Thus the turbines can only be activated for some 2,700 hours a year. As conceived at present, the flow would be scheduled to coincide with periods of peak demands for electricity, when hydroelectric power would supply 10% of Israel's estimated electricity requirements (in 10 years' time). Should other power stations be put temporarily out of action, however, the turbines could be kept in operation for an extended period, after which they would have to be shut down for two or three years while the Dead Sea 'dried up'.

The substantial quantities of water flowing through the proposed tunnel, planners say, could also be used for cooling purposes by nuclear power stations, making it possible to build them away from the crowded seashore.

● Israel does not yet have a nuclear power station on the coast—or anywhere else for that matter—but every 'nuclear development' in the country arouses interest, often for the wrong reasons. This was demonstrated once again a few weeks ago when a Dutch newspaper printed a photograph of a tower-like object and captioned it as follows: "A new nuclear energy installation is being completed near Tel Aviv. No details about this installation at the Weizmann Institute are known. However, the great powers are not only interested, but also worried about Israel's growing atomic strength."

In point of fact, the object shown is the 19-storey Koffler Accelerator Tower, next year to house a 14-UD Pelletron accelerator.

Far from being a secret facility, the Pelletron will be open to scientists from around the world. Indeed the first large international group to visit the site—participants in the recent Third Tandem Accelerator Conference—were there at the same time the Dutch newspaper was making its mistake.

● While Israeli physicists concern themselves, for the most part, with basic research, Israelis in the biomedical field generally concentrate on the solution of day-to-day problems. Such is the case with Professor Bruno Lunenfeld, Director of the Institute of Endocrinology at the Sheba Medical Centre, near Tel Aviv. Professor Lunenfeld, for example, has developed a method that enables previously childless Orthodox Jewish women to have children without violating the tenets of family purity as laid down by traditional Judaism.

For an Orthdox woman, sexual intercourse is only permitted during a limited period each month. It can begin only seven days after the end of her menstrual period, until when she is regarded as 'unclean'. In ordinary circumstances, this does not prevent her from becoming pregnant, but if a woman's menstrual period extends beyond the usual five days, or her menstrual cycle is less than the usual 28 days, her days of greatest fertility may occur during the time when she is 'unclean' and therefore forbidden to her husband.

Professor Lunenfeld found that this problem can almost always be solved, once the religious woman's most fertile days are determined, by giving her an anti-oestrogenic substance known as clomiphene citrate. As a result, ovulation is delayed long enough to occur when the woman is permitted by the laws of family purity to have intercourse. Ironically, this substance was originally developed as a means of birth control, but is now used primarily to induce ovulation in infertile women.

Incidentally, Moslem women have also benefited from the treatment. Subject to even more severe laws of purity than are their Jewish sisters, the anti-oestrogenic substance has saved many of them from childlessness, a particularly tragic fate in traditional Moslem society.

● In another part of the Sheba Medical Centre, Dr Dan de-Medina is using the techniques of biofeedback to treat veterans of the Yom Kippur War.

Dr de-Medina, whose professional career began with a cancer research team and later continued in the sphere of memory studies, first delved into biofeedback when on an extended visit to the USA in 1973. He arrived back in this country, fortuitously, shortly before the outbreak of the Yom Kippur War, in the wake of which hundreds of men suffered from post-traumatic neuroses. And in spite of the fact that biofeedback techniques had never previously been used in Israel for the treatment of such neuroses, Dr de-Medina was allowed to use them with some of the badly shaken war veterans.

He found, as did others dealing with this problem, that it was more common and more severe than it had been after previous wars, presumably because the fighting had lasted longer and because the outcome had been less clear-cut (the euphoria of a great victory apparently has a healing effect). The patients sent by the army to Dr de-Medina generally returned to relative normality more quickly than those treated by other techniques, some of which, unlike biofeedback, involve the possible creation of drug dependence.

The method used by Dr de-Medina (and overseas practitioners) is quite simple It involves connecting up the patient to a 'Galvanic Skin Response Feedback' instrument, not unlike a lie detector, which registers anxiety on a scale or by the sounding of a siren. After a period of conditioning, usually involving some 20 sessions, the patient finds he is able by his own efforts to reduce the number registered on the scale or the pitch of the siren and, almost as a side effect, to lessen his sense of anxiety Finally, he gains a conditioned reflex whereby anxiety is switched off, without the benefit of the instrument.

Industry and Academics

Sir,—I would like to comment on your leading article "Why industry and academics go their separate ways" (September 25).

Whereas in the large industrial countries, in spite of the problems cited in the article, there is probably always enough dialogue between research and industry to produce good results, in small countries like Norway scientific effort has to be very carefully husbanded. They cannot afford the luxury of *laissez faire* in research and development, and somehow they have to overcome the pre-development, evaluation and identification gaps, even if they don't satisfactorily solve them.

I have been living for much of the past 12 years in Norway, working in, or in the closest vicinity of, an interesting semi-academic institution which represents one solution to the problem presented in your article. This institution has been in existence for 25 years now, is still flourishing, and is therefore perhaps worthy of mention. It consists of a contract organisation by the name of SINTEF, situated on the campus of the Norwegian Technical University. It has a staff of some 650 people, of whom 350 are university graduates or the equivalent. In that it works hand-in-glove with the university, it is instrumental in keeping the latter in close touch with industrial trends, and in that most of its income is derived from industrial projects, it is unable itself to stray too far from industrial needs.

SINTEF is a non-profit-distributing organisation, with a board consisting of academics and industrialists. Money from the National Research Council is obtained largely according to the project in hand, and often on a 50–50 basis with an industrial partner Good ideas generated internally are backed internally until ripe enough for presentation to industry, at which point they are then, in the ideal situation, developed into a marketable product at industry's expense Good ideas, or requirements, from industry are brought to SINTEF for fundamental development because the latter has by now built up a solid reputation for quality, timeliness and (believe it or not) budget consciousness. A fairly thorough presentation of SINTEF will be published shortly in the *European Journal of Engineering Education.*

I often ask myself why this tripartite symbiosis actually works, and I think there are at least three good reasons. First, the university is not isolated from industry as so many are in larger countries. Second, a substantial number of research-oriented people get a great kick out of seeing their ideas actually transformed into a product, ensuring an adequate supply of employees. And third, Norway actually benefits from being small in that industry knows what SINTEF is, and can very easily get in touch with the appropriate people.

If there is a fourth important reason, I would say it is that a country like Norway simply doesn't have the national resources to turn research and development into a holy cow. Apply your research or starve. Perhaps one of the salutary results of Britain's tragic situation today will be precisely this.

Norman Sanders

Trondheim, Norway

EEC directives

Sir,—Eric Ashby (October 16) says that "all pollution except that from atomic weapons is a by-product of processes which benefit society".

Lord Ashby must have walked sometimes through a busy street and been assailed by a barrage of traffic noise from cars and heavy lorries (all necessary?) and breathed in their exhaust fumes. Perhaps he might have gone into a restaurant or cinema and filled his lungs with tobacco smoke. There is a vast amount of packaging of food in plastic and the like, much of it for the sake of advertising. Many people are engaged for eight hours or more per day with sheer monotonous routine work making products which have more to do with status than with benefit. Can Lord Ashby honestly believe, therefore, that much of what is manufactured in our society is beneficial?

Why is it a phony argument for the EEC to assert that a Scottish mill discharging into the Atlantic will unfairly compete with a mill on the Rhine which has to comply with stringent standards? Surely, if a uniform standard were not applied to all factories, then only those factories which could pollute the environment unabated would remain in existence while others under stringent control would go out of business. After all, Lord Ashby did mention that he was in argeement with the EEC's long term objective concerning the purity of the sea.

Lord Ashby did not like the idea of regular monitoring of the beaches for pollutants, and his main objection was that it would cost £100 million a year (a guess by the Department of Environment). He supports his objection by mentioning a report made by the Medical Research Council in 1959 which stated that, in spite of the smelliness and ugliness of many beaches, they were not a hazard to health. Even if the conclusion of the report were absolutely correct, has a report published 16 years ago any relevance to what is happening today and could happen in the future as regards the pollution of the sea?

The gist of Eric Ashby's article seems to me to be: 'We're not going to let a lot of foreigners tell us what to do'. The 'foreigners' seem, however, to be much more willing to tackle pollution than do the powers that be in Britain.

Paul C. French

Blommenholm, Norway

A hundred years ago

At last Friday's lecture by Dr. Carpenter, in connection with the St. Thomas Charterhouse School Teachers' Science Association, Dr Lyon Playfair presided. In proposing a vote of thanks to Dr. Carpenter, Dr. Playfair referred to the subject of compulsory education, which is gradually becoming universal in this country, but which, he said, would be pure tyrrany unless the education in our schools was increased and its quality raised Quantity is all very good, but unless there is quality along with it, there is not much gained "If it was to be said that children of thirteen or fourteen years of age were merely to receive the same education would be but tyranny. Therefore compulsory education involved higher education." Dr. Playfair expressed his gratification that the teachers composing the Association had banded themselves together in order to qualify themselves by attending such lectures as those of the Gilchrist fund and by other means, to undertake this higher education, which, we believe with Dr. Playfair, will be forced upon us even in elementary schools by the spread of compulsory education.

Humoral factors in myasthenia gravis

from Vanda Lennon

IN 1905 Buzzard speculated that the symptoms of myasthenia gravis (MG) might be caused by an "autotoxic agent which has a special influence on the protoplasmic constituent of voluntary muscle" (*Brain*, **28**, 438). Today two distinct protein entities have been identified as potential candidates for the role of the "autotoxin" mediating neuromuscular blockade in MG: antibody to acetylcholine receptor (*News and Views*, *Nature*, **256**, 10; 1975) and thymopoietin (formerly called thymin), a polypeptide derived from the thymus (Goldstein and Schlesinger, *Lancet*, **ii**, 256, 1975).

Purification of nicotinic acetylcholine receptor protein (AChR) from the electric organs of *Electrophorus electricus* and *Torpedo californica* allowed the establishment of an animal model of MG—experimental autoimmune myasthenia gravis (EAMG) (Patrick and Lindstrom, *Science*, **180**, 871; 1973; Lennon *et al.*, *J. exp. Med.*, **141**, 1365; 1975; Tarrab-Hazdoi *et al.*, *Nature*, **256**, 128; 1975). EAMG is readily induced in mammals by immunisation with AChR and resembles spontaneously occurring human MG by every criterion examined so far. Clinically, muscle weakness, fatigability and improvement by anti-cholinesterase drugs occur. Electrophysiologically, a decrementing response of muscle to motor nerve stimulation occurs at low rates of stimulation (2–10 s^{-1}) and rapid repetitive stimulation induces post-activation facilitation followed by exhaustion—phenomena which occur in MG The electrical defect is repaired by anti-cholinesterases and sensitivity to curare is pronounced (Seybold *et al*, *Ann. N.Y. Acad. Sci.*, in the press). The amplitude of miniature end-plate potentials (mepp's) is reduced, but the number of transmitter quanta released by a nerve impulse and the stores of acetylcholine quanta immediately available for release by nerve impulse are normal (Lambert *et al.*, *Ann. N.Y. Acad. Sci.*, in the press). Ultrastructurally, motor end-plates of rats with chronic EAMG are indistinguishable from those of patients with MG, the post-synaptic membrane being the primary target of the autoimmune reaction (Engel *et al.*, *J Neuropath, exp Neurol.*, in the press).

The critical link between EAMG and MG has been the finding of antibody to AChR in the serum in both conditions (Almon *et al.*, *Science*, **186**, 55; 1974; Aharonov *et al.*, *The Lancet*, **2**, 340; 1975; Lindstrom *et al.*, *Ann. N Y. Acad. Sci.*, in the press). Using human muscle AChR as antigen, Lindstrom and coworkers have found that anti-receptor antibody is specific for MG, being present in 87% of 71 MG sera tested (and also in newborn infants of a myasthenic woman) and in none of 156 subjects with other neurological, autoimmune and endocrine diseases. Interestingly, this antibody, like that in EAMG, is not directed at the acetylcholine binding site of the receptor. *In vitro* studies have shown, however, that anti-AChR antibodies from animals with EAMG diminish acetylcholine sensitivity of muscle fibres, reduce the mepp amplitudes and decrease the ability of AChR *in situ* to bind α-bungarotoxin (Green *et al.*, *Proc. R. Soc. Lond.*, **189**, 57; 1975).

Thymopoietin is a polypeptide which has recently been purified from bovine thymus (Goldstein, *Nature*, **247**, 11; 1974) and synthesised (Schlesinger *et al.*, *Cell*, **5**, 367; 1975). This polypeptide was named for its unequivocal capacity to induce bone marrow cells *in vitro* to express differentiation antigens characteristic of thymocytes (Basch and Goldstein, *Proc. natn. Acad. Sci. U S.A.*, **71**, 1474; 1974). Additionally thymopoietin is reported to have an effect *in vivo* on neuromuscular transmission (Goldstein, *Lancet*, **ii**, 119; 1968; Goldstein and Schlesinger, *ibid.*, **ii**, 256; 1975). When thymopoietin was given to mice intraperitoneally in nanogram amounts an apparent neuromuscular block (which did not increase with increasing doses) was found between 18 h and 5 d later. This contrasts with the effects of cobra venom toxins which block AChR *in vivo;* in rats these toxins cause weakness, which is dose related, and electromyographic decrements typical of MG beginning within 10-60 min and reaching a maximum by 3-13 h (Satyamurti *et al.*, *Science*, **187**, 1975; Lennon *et al*, *J. exp. Med.*, **141**, 1365; 1975). The characteristics of the decrement ascribed to thymopoietin have not been reported and are not evident in the short published record. Unfortunately, the defect was demonstrated at a stimulation rate of 50 s^{-1}, a rate at which artefacts are difficult to avoid; stimulation rates of 2-5 s^{-1} are optimal for demonstrating decrements in the diagnosis of MG (Slomic *et al.*, *Brain Res.*, **10**, No. 1; 1968; *New Developments in Electromyography and Clinical Neurophysiology*, Desmedt, J., ed., **1**, 241–304, Karger, Basel; 1973). Thus, the mechanism of action of this interesting polypeptide requires detailed electrophysiological analysis but its relevance to MG is far from clear.

What then is the role of the thymus in myasthenia gravis? Abnormalities of the thymus (hyperplasia and tumours) are often found in association with MG, and selected patients benefit from thymectomy. About 30% of patients with MG have antibodies, demonstrable serologically, which react with striations of skeletal muscle and with similar elements in the thymus, the "myoid" cells. Nicotinic AChR also has been identified in the mammalian thymus (Lindstrom *et al.*, *Ann N.Y. Acad Sci.*, in the press; Aharonov *et al.*, *Proc. natn. Acad. Sci. U.S.A.*, **72**, 1456; 1975) Thymuses of patients with MG typically have germinal centres, which are the hallmark of antibody production and are not normally present in primary lymphoid organs. Thus it is not surprising that MG thymuses contain a large proportion of B lymphocytes (Abdou *et al.*, *New Engl. J.*

Med, **291**, 1271; 1974) and that in tisue culture MG thymocytes, in contrast to normal human thymocytes, synthesise considerable quantities of immunoglobulin (Smiley *et al.*, *Clin. exp. Immun.*, **4**, 387; 1969). It has yet to be ascertained whether this immunoglobulin is anti-AChR antibody, which would mean that in MG the thymus is a site of autoantibody production. It was the presence of germinal centres in MG thymuses that initially led Goldstein to propose that the primary lesion in MG was an autoimmune "thymitis" which led to the release of large amounts of thymopoietin. Goldstein and Whittingham (*Lancet*, **2**, 315; 1966) reported induction of histological signs of "autoimmune thymitis" in experimental animals by immunisation with saline extracts of muscle and thymus tissue in adjuvant. Those animals had no signs of weakness but did exhibit an electromyographic abnormality similar to that described in the subsequent thymopoietin studies. Small reductions in the amplitudes of mepp's were reported in rats with "thymitis" (Goldstein and Hofmann, *J. Neurol. Neurosurg. Psychiatr.*, **31**, 453; 1968). The reduction in amplitudes was much smaller than that observed in patients with MG or in rats with EAMG. Blind studies and attention to details such as differences in input resistance would seem essential in assessing the significance of the small differences reported in rats with "thymitis". On the basis of observations in EAMG, rats with so little reduction in mepp amplitudes would not be expected to show decrementing electromyograms. Considerable controversy has surrounded the model of "experimental autoimmune thymitis", some authors claiming confirmation of Goldstein's findings (Kalden *et al.*, *Clin. exp. Immunl.*, **5**, 319; 1969; Kawanami and Mori. *ibid.*, **12**, 447; 1972; Mrozek and Kaminska, in *Structure and Function of Normal and Diseased Muscle and Peripheral Nerve*, (edit. by Petrusewicz, I., and Jedrejowska, H., 145 Polish Medical Publishers, 1972), others failing to confirm the findings (Vetters *et al.*, *Lancet*, **2**, 28; 1969; Kaufman *et al.*, *J. Neurol. Neurosurg. Psychiatr.*, **32**, 281; 1969; Jones *et al.*, *J. Neurol. Neurosurg. Psychiatr.*, **34**, 399; 1971). It seems imperative that the effects of thymopoietin on neuromuscular transmission now be re-examined and documented in as convincing a manner as have been its T-lymphocyte differentiating properties. ☐

Teratocarcinoma cells can develop normally

from Brigid Hogan

TERATOMAS and teratocarcinomas are rare tumours which arise in the gonads, and contain a whole variety of differentiated tissues of ectodermal, mesodermal and endodermal origin (such as skin, nerve, muscle, cartilage, gut and lung), mixed together in a disorganised mass. Although tissue culture lines of teratocarcinomas have been available for many years, it is only recently that technical progress in studies of the biochemical properties and *in vitro* differentiation of these cells has enabled their potential as a model for early mammalian development to be assessed (for a recent review, see Martin (*Cell*, **5**, 229–243; 1975). The paper by V. E Papaioannou *et al* in this week's *Nature* (page 70) now elegantly confirms and extends the key observations that, placed in the environment of the early embryo, teratocarcinoma cells are in fact able to participate in normal morphogenesis and differentiation.

The study of teratocarcinomas was first put on a modern scientific basis in the late 1950s by Leroy Stevens in the Jackson laboratory, who noticed that the 129/Sv strain of mice had a high frequency of spontaneous testicular teratocarcinoma. Stevens and his colleagues showed that the tumours arose from germ cells in the testis and were retransplantable in either a solid or ascites form so long as nests of undifferentiated "embryonal carcinoma" cells were included in the inoculum; in the absence of these cells the transplanted tissue formed a slow-growing, benign, teratoma. The ascites form of the tumour consists of numerous small "embryoid bodies" floating in the ascites fluid; the simplest of these aggregates are made up of an outer layer of endoderm cells surrounding a core of embryonal carcinoma cells. This curious arrangement is in fact strikingly similar to the organisation of very early mouse embryos. At 4 days after fertilisation the normal blastocyst consists of a hollow trophoblastic vesicle enclosing a cluster of about 15 cells known as the inner cell mass (ICM); by 4.5 days the outer layer of the ICM differentiates into endoderm cells (which later form the extra-embryonic yolk sacs), while the internal cells go on to form ectoderm and mesoderm (the origin of the embryonic endoderm is at present unclear) Later work from a number of laboratories established that transplantable teratocarcinomas could also be obtained from many different strains of mice by injecting (male or female) embryos of up to 7 days development (but not older) into extrauterine sites such as the kidney capsule.

When embryoid bodies of either testicular or embryo-derived tumours are cultured *in vitro* they attach to the dish and cells proliferate out to form a multi-layered sheet within which a whole range of differentiated tissues gradually develop (Teresky *et al.*, *J. Cell Physiol.*, **84**, 319–332; 1974, and Gearhart and Mintz, *Cell*, **6**, 61–66; 1975, for recent examples of this process). Single embryonal cells can also be isolated from embryoid bodies and used to obtain a clonal population of homogeneous cells which remain undifferentiated over many generations, so long as they are prevented from forming dense aggregates. The majority of these cells retain a normal mouse karyotype and have several morphological, biochemical and cell surface properties (review by Artzt and Bennett, *Nature*, **256**, 545–547; 1975) in common with cells of the early mouse embryo.

Recently, G. R. Martin and M. Evans showed that if teratocarcinoma cells are allowed to form floating aggregates, the outer layer differentiates to form endoderm (*Proc. natn. Acad. Sci.* U.S.A., **72**, 1441–1445; 1975). So far, sorting out or differential proliferation of two cell populations has not been rigidly excluded. It seems more likely, however, that the cells on the outside of the aggregate receive a signal triggering them to differentiate as endoderm, a process which also happens during the normal development of the 4–4·5 day ICM. (Rossant, *J. Embryol. exp Morph.*, **33**, 991–1001; 1975). What kinds of signals are responsible for triggering such changes in cell committment is a crucial question in developmental biology, and if teratocarcinoma cells are to be of any use in solving the problem it is important to show that they are equivalent to embryonic cells in their ability to participate in normal morphogenesis and differentiation when placed in the environment of the early embryo. The first indication that such participation could occur was provided by R. L. Brinster (*J exp. Med.*, **140**, 1049–1056; 1974) who injected embryonal carcinoma cells from simple embryoid bodies from ascites fluid into 4 day mouse blastocysts of a different genotype and obtained one chimaeric animal. At a meeting held in May of this year at the Roche Institute, New Jersey, B. Mintz announced that she had successfully repeated this experiment, testing for chimaerism with several different genetic markers. In the experiments reported by Papaioannou *et al.* three lines of teratocarcinoma cells cultured *in vitro* have been used as a source of donor cells and out of 121 animals born from inoculated blastocysts 11 showed evidence for chimaerism as judged by glucose phosphate isomerase isozyme, melanin and agouti markers. A proportion of the chimaerae from one cell line developed tumours, and some tissues (blood for example) do not appear to be chimaeric, but overall these results are very good evidence that at least some cultured teratocarcinoma cells are able to participate in normal development. As Papaioannou *et al.* point out, one implication of their experiment is that it should now be possible to select mutants of the cultured cells and use them to study metabolic cooperation and cell interaction during development. ☐

Mismatched DNA and recombination

from a Correspondent

It is now generally accepted that structures containing regions of heteroduplex DNA, with one strand of the duplex contributed from each parent molecule, are essential intermediates in the biochemically complex process of genetic recombination. During heterozygous crosses, the inclusion of a genetic marker within such a hybrid segment of DNA will mean the formation of a mismatched base-pair, or some other localised distortion of the DNA structure. It has been clearly shown in several systems that localised aberrations in DNA structure are subject to enzymic repair, by processes presumed to be analogous to the excision of pyrimidine dimers from ultraviolet-irradiated DNA. This repair of heteroduplex mismatches is believed to be a fundamental step in the recombination process and to be primarily responsible for the unequal segregation of the components of an allele-pair in the process of gene conversion.

Ahmad, Holloman and Holliday, in this week's issue of Nature (page 54) have now demonstrated that a nuclease from the smut fungus, *Ustilago maydis*, which had previously been implicated in genetic recombination, has the properties expected of an enzyme involved in the repair of mismatching heteroduplices.

The enzyme, DNase I, purified from extracts of wild-type *U. maydis*, introduces single-strand breaks in linear, duplex and DNA molecules and reduces linear, single-stranded DNA to small oligonucleotides (Holloman, *J. biol. Chem.*, **248**, 8114; 1973). Ahmad *et al.* have now studied the activity of the nuclease towards linear duplex DNA molecules containing local distortions, using heteroduplex molecules made from the separated strands of the DNA of bacteriophage SPP1. The state of the DNA can be sensitively monitored through its efficiency in the formation of infectious centres on transfection of competent cells of *B. subtilis* Spatz and Trautner, who previously used this system to study the *in vivo* repair of heteroduplices (*Molec. gen. Genet.*, **109**, 84; 1970), have shown that a single-strand nick inactivates the DNA molecule in the transfection assay.

During a standard exposure of the DNA to the nuclease, the extent of inactivation of heteroduplices containing a single base-pair mismatch is about 6-fold greater than that of the homoduplices. Heteroduplices containing a small deletion on one strand are better substrates than those containing single base-pair mismatches. Thus the *Ustilago* enzyme is clearly able to recognise and preferentially attack those molecules containing distortions of the bi-helical structure. The nature of the biologically inactive products of the enzymic reaction was not investigated.

Well characterised nucleases from *Neurospora crassa* and *Aspergillus oryzae* have many similarities to the *Ustilago* enzyme, including the marked specificity for polynucleotides with disordered structures. The novel feature of the *Ustilago* enzyme is that it is strongly implicated in genetic recombination. Double mutants of *Ustilago*, isolated by screening for deficiencies in both extracellular and intracellular doexyribonucleases, show no detectable allelic recombination (Badman, *Genet. Res*, **20**, 213; 1972) and much reduced DNase I activity (Holloman and Holliday, *J. biol. Chem*, **248**, 8107–8113; 1973). The presumption that the deficiency in recombination and the loss of deoxyribonuclease activity are due to the same genetic lesions is supported by the finding that the two phenotypes are segregated together through meiosis.

The unusual specificity of these fungal nucleases makes them of more general interest as tools in molecular genetics. Their value is strikingly illustrated in a recent paper by Shenk, Rhodes, Rigby and Berg (*Proc. natn. Acad. Sci. U.S.A.*, **72**, 989–993; 1975) who have used the *Aspergillus* nuclease, S1, to analyse mutations in the genome of the monkey virus, SV40.

Shenk *et al.* demonstrates that the S1 nuclease specifically hydrolyses linear heteroduplices of SV40 DNA at the position of a single-strand nick, a small denaturation loop or even, in some cases, a single base mismatch. This property should have remarkable ramifications in molecular genetics, since it potentiates accurate localisation of genetic lesions in systems devoid of genetic recombination and of lesions that cause no phenotypic change. It should also facilitate the isolation of small, discrete segments of a genome in the many cases where the segment can be bounded by two suitable mutations. Satisfactory S1 nuclease is already commercially available!

Evolution of tolerance to pollution

from Peter D. Moore

Although attention has recently been paid to the influence of pollutants on the structure and metabolism of whole ecosystems (for example Woodwell, *Science*, **618**, 429; 1970), the effects of pollution on species composition have been the subject of rather more research Detailed observational studies, such as those of Hawksworth and Rose (*Nature*, **227**, 145; 1970) on epiphytic lichens have even made it possible to estimate ambient pollution levels from the species composition of communities. Such studies demonstrate that different species differ in their tolerance to a given pollutant, some responding at lower thresholds than others But even within populations of a single species, the presence of a pollutant in the environment selects against those individuals which are most sensitive to it. This has been demonstrated most effectively in the evolution of heavy metal tolerance in grasses near abandoned mines (Antonovics, Bradshaw and Turner, *Adv. Ecol. Res.*, **7**, 1; 1971), but an increasing amount of evidence suggests that air pollutants are exerting a similar influence.

The classic work of Kettlewell (see *The Evolution of Melanism*, Clarendon Press, Oxford, 1973) on the development of melanism as a response to air pollution by particulate matter, has demonstrated that such selection occurs among insect populations The problem can be a complex one, however, as has been shown recently in the case of the two spot ladybird (*Adalia bipunctata*). Creed (*Nature*, **249**, 391; 1974) described the high incidence of melanism in this species in areas of high smoke pollution. He showed a distinct negative correlation between the frequency of melanic forms and the distance from a smoke-emitting 'Phurnacite' plant, which produces smokeless fuel from coal, in the valleys of South Wales. Subsequently, however, an alternative explanation of this correlation has been put forward by Muggleton, Lonsdale and Benham (*J. appl. Ecol.*, **12**, 451; 1975). They have reconsidered the distributional evidence and come to the conclusion that melanism in the two spot ladybird is more closely related to the duration of sunshine in any area, which, in turn, is likely to be affected by smoke levels. They supplement this with experimental evidence that the temperature of the melanic form rises more rapidly when exposed to a given level of radiation, thus providing it with a metabolic advantage in conditions of low insolation.

Recent work among plants has concentrated upon sulphur dioxide as an air pollutant. About 6 million tonnes of SO_2 are emitted into the atmosphere over Britain each year; thus it constitutes one of our major air pollutants. Prolonged exposure to low concentrations of SO_2 (below about 15 p.p.hm) does not seem to harm most plants, although depressed yield in ryegrass variety S23 (*Lolium perenne*) has been reported in experiments conducted at SO_2 levels below this (Bell and Clough, (*Nature*, **241**, 47; 1973). Since one of the most noticeable effects of SO_2 on plants is to cause increased stomatal opening (Unsworth, Bisco and Pinckney, *Nature*, **293**, 459; 1972), its deleterious influence may be indirect in allowing other toxic gaseous pollutants to enter the leaf tissue.

Sulphur dioxide pollution thus places a stress upon plant species and selects against those individuals in a population which are least tolerant. The effectiveness of this selective force has recently been demonstrated by the work of Taylor and Murdy (*Bot. Gaz.*, **136**, 212; 1975) in the vicinity of a coal burning power station in Georgia, USA. Seed was collected from a winter annual species, *Geranium carolinianum* at sites close to the station and at control sites some distance away, where SO_2 pollution was not a major stress. Nine weeks after germination, the plants were subjected to 12 h exposure to an atmosphere containing 80 p.p.hm SO_2. Three days later leaf damage was assessed for each individual on the basis of mean percentage leaf area showing necrosis. The method of assay should overcome the differential absorption of SO_2 which occurs in leaves of different ages (Craker and Starbuck, *Environ. Res.*, **6**, 91; 1973)

Frequency distributions of plants with varying degrees of leaf damage show a very considerable spread in all populations. It is to be expected that material derived from seed should exhibit wider variation than would the mature plants, since the latter would have been subjected to selection during establishment and maturation. Nevertheless, statistically significant differences were demonstrated between the mean leaf area damaged in populations near to and far from the source of SO_2 pollution. Differences were generally of the order of 10% less damage to the populations found close to the power station.

One can conclude, therefore, that there is a greater degree of tolerance to acute SO_2 pollution in the populations of *Geranium carolinianum* growing near a source of SO_2. It would be interesting to examine the relative tolerances of the populations to chronic exposure to lower SO_2 concentrations and to find out precisely what physiological adaptation is involved in the tolerance. This work indicates that very rapid selection (the power plant in question is just 31 years old) can occur amongst annual species, when subjected to a new environmental stress.

Transfer factor in viral infections

from Arie J. Zuckerman

THE transfer of cell-mediated hypersensitivity to tuberculin and streptococcal antigens was first achieved in man using blood leukocytes by Lawrence (*Proc. Soc. exp. Biol.*, **71**, 516; 1949). These observations in turn led to the finding that leukocyte extracts were as effective as viable cells for the transfer of delayed-type hypersensitivity. But these apparently innocent observations betray the controversy which surrounds transfer factor and which resulted in such sensational headlines as "Transfer Factor—science or magic?" (*New Scientist*, September 12, 1974) and "Transfer Factor—another scandal?" (*loc cit*, December 26, 1974). F. M. Burnet wrote recently:

> "Widespread recent interest in the transfer factor of H. S. Lawrence and its possible therapeutic applications has not yet led to an interpretation of the phenomenon that can bring it into a satisfactory relationship with standard immunological theory. The specificity of transfer factor (TF) has been demonstrated in the sense that only a small proportion of the lymphocytes in a recipient can respond to a given TF preparation. The active agent in TF is known to be of low molecular weight (4,000 to 5,000), but its chemical nature and the basis of its specificity are unknown. Neither is anything known about the cell receptor that must be capable of specific reaction with a particular TF. An hypothesis is developed which sees the biological function of TF as to recruit T lymphocytes to deal with situations such as delayed hypersensitivity or allograft rejection reaction for which there are inadequate numbers of immunologically reactive lymphocytes Although the specificity of TF does not appear to be related to immunological specificity, it calls for a genetically based generation of diversity roughly analogous to that required in the development of the immune system" (*J. Allergy clin. Immun*, **54**, 1; 1974)

The factual background to the controversy surrounding transfer factor is as follows. Transfer factor may best be described as a dialysable leukocyte extract that initiates and augments delayed-type hypersensitivity and cell-mediated immunity in normal persons, and Lawrence (*Adv. Immun.*, **11**, 195; 1969) considered transfer factor to be an antigen-specific polypeptide–polynucleotide molecule. Gottlieb *et al.* (*Lancet*, **2**, 822; 1973) found, however, that crude leukocyte dialysate from donors sensitive to *Candida* consisted, after concentration and elution from a column of Sephadex G 10, of three fractions, one of which was more active than the crude transfer factor. This fraction had a density of 1.47 g ml^{-1} in caesium sulphate and the properties of a short polypeptide chain consisting of perhaps 12 amino acids joined to 3 or 4 RNA bases in a ratio of 2: 1. The molecular weight of transfer factor is less than 10,000, probably 2,000—4,000. It is resistant to trypsin and mammalian DNase and RNase and the ultraviolet spectrum indicates the presence of polypeptide moieties. It is not related to any immunoglobulin class and it is non-immunogenic in man or animals. The present concept of transfer factor is therefore that of a soluble indicator of cellular immunity, for example an informational polynucleotide or a specific gene derepressor, which instructs previously uncommitted lymphocytes to become specifically sensitised and thereby transfers the state of delayed hypersensitivity. It has been suggested that cellular cooperation between T lymphocytes, B cells and macrophages may be associated with lymphokine factors and transfer factor for the induction of delayed hypersensitivity and antibody synthesis or in cytotoxic activity against cells with viral, tumour or histocompatibility antigens (Playfair, *Clin. exp. Immun.*, **8**, 839; 1971). In fact, Dumonde and Maini (*Clin. Allergy*, **1**, 123; 1971) suggested that, in the presence of a specific antigen, transfer factor induces non-sensitised lymphocytes to produce lymphokines.

Clinically, transfer factor activates uncommitted and non-sensitised lymphocytes of the recipient so that new clones of antigen-specific cells are produced. Besides conferring specific skin sensitivity, these cells may also produce interferon and other biologically active products which, as a result of non-specific stimulation, may contribute to the overall pattern of the cellular immune response in the recipient. It should be noted that transfer factor seems to be exceedingly potent; the amount of factor required to confer systemic skin reactivity on a normal recipient is the extract of only 0.1 ml of packed leukocytes. Reactivity to the other antigens to which the donor was sensitive, such as *Candida,* mumps, streptococcal and other antigens, is transferred simultaneously. But transfer of the capacity for antibody formation does not occur.

The clinical use of transfer factor is based on the view that depressed cell-mediated immunity is of pathogenic importance in various disease states and that, by reversing the deficiency, transfer factor can ameliorate the disease process. This has been tested in severe infections caused by mycobacteria, fungi and viruses, particularly in patients with defective lymphocyte responsiveness either *in vivo* or *in vitro.* On the same basis it has been possible to correct certain primary immunodeficiency states in some patients exhibiting selective depression of lymphocyte function.

Patients suffering from a number of infectious diseases, including mucocutaneous candidiasis, coccodioidomycosis, leprosy and a number of viral infections, have been treated with transfer factor. The patients responded to treatment with transfer factor obtained from donors in whom skin tests to the particular antigen were strongly positive. Successful outcome has been reported in a few patients with generalised vaccinia, herpes zoster, neonatal herpes virus infection, measles "giant-cell" pneumonia and subacute sclerosing panencephalitis.

Spitler and colleagues (*Clin. Immunobiol.,* edit by Bach, F. H., and Good, R. A., Academic Press, 1974, p. 153) treated a number of patients with verruca vulgaris, an example of a chronic viral infection, with transfer factor pooled from normal donors presumed to have immunity to this virus. Clinical improvement occurred in only one patient after several months of therapy so that the improvment may be quite unrelated to the use of transfer factor. A note of caution was added recently by Stevens and his associates (*Clin. exp. Immun.,* **21,** 520; 1975). Dialysed transfer factor, prepared from the leukocytes of a donor whose warts had undergone spontaneous regression, was used in the treatment of a child with Wiskott–Aldrich syndrome, a congenital immune deficiency. The child then had a spontaneous regression at multiple areas with warts. A similar relationship was observed in a pilot study in four otherwise healthy patients. But a randomised double-blind study of thirty patients failed to confirm a causal relationship between therapy with transfer factor and wart regressions.

Attention has also been directed recently to persistent infection with hepatitis B virus. Kohler and his colleagues (*Clin. Immun Immunopathol.,* **2,** 465; 1974) treated a healthy persistent carrier of hepatitis B surface antigen with lymphocytes from an individual who had recovered eight months previously from hepatitis B. Within 24 h there was an increase in the titre of antigen and of serum aspartate transaminase levels, an indication of liver damage. It was suggested that the recipient's liver cells were transiently injured by a cell-mediated immune response, which was insufficient to terminate the infection. Transfer factor prepared from the same donor had no effect on the patient's liver function tests. The biological activity of this material, however, was not evaluated and it may have been inactive. Another patient, an infant who acquired hepatitis from her mother at birth, was given transfer factor prepared from the mother's lymphocytes. On two occasions the preparation caused a prompt, moderate increase in both the antigen and transaminase levels. Subsequently, the liver function tests became normal and the titre of hepatitis B surface antigen was reduced by 95%. It is generally considered that cell-mediated immunity is important in terminating hepatitis B infection. Temporary falls in the levels of hepatitis B antigen have also been reported after the use of transfer factor in a few patients with antigen-positive chronic active hepatitis. Jain and his colleagues reported at the meeting of the British Society of Gastroenterology held in Oxford in September, 1975, the results of treating three patients with "specific" transfer factor prepared from subjects recently recovered from hepatitis B infection. One patient with chronic active hepatitis, and cirrhosis associated with antigenaemia showed no response to transfer factor prepared from a normal blood donor but "specific" transfer factor increased the number of T lymphocytes; a second similar patient also showed no response to "normal" transfer factor but "specific" transfer factor increased transiently the serum aspartate transaminase levels suggesting stimulation of cell-mediated immunity with a resulting hepatitic reaction. The third patient suffered from antigen-positive active chronic hepatitis complicated by primary liver cancer; he was receiving corticosteroid therapy and did not respond to transfer factor. It was concluded that although there was no alteration in the serum titres of hepatitis B surface antigen further trials wtih transfer factor seem justified.

Finally, Bullock *et al.* (*New Engl. J. Med.,* **287,** 1053; 1972) pointed out that there is a risk of transfer factor exciting generalised hypersensitivity reactions to disseminated microbial or other antigens and that, paradoxically,

---

Earthquakes without precursors?

from Peter J. Smith

SOME shallow earthquakes are known to be preceded by significant decreases in P and S wave velocities (V_p and V_s) and the seismic velocity ratio V_p/V_s. One of the problems in using these effects as a basis for earthquake prediction, however, is that not all shallow shocks appear to give such warning. Reasons proposed so far for the lack of premonitory effects in certain cases range from failure to measure V_p and V_s at the appropriate times to possible variations of the V_p, V_s and V_p/V_s decreases when measured in different directions with respect to the trend of elongated cracks in the surrounding rock. But two new experiments carried out by Wang *et al.* (*Geophys. Res Lett.,* **2,** 309; 1975) now suggest that the apparent presence or absence of precursory phenomena may depend not simply on observational arrangements but on something much more fundamental.

In the first experiment, a block of dry 'Westerly' granite with an imposed normal load was subjected to an increasing shear load until fracturing occurred. Both V_p and V_s for waves travelling normal to the shear plane decreased before rupture, and dilation took place in the same direction V_p/V_s decreased from a 'normal' value of 1.7 to 1.4 in line with previous field and laboratory observations. In the second experiment, the granite block was first sliced in half and then subjected to normal and shear stresses to give stick-slip motion. But no V_p and V_s changes were observed either before or during sliding, and there was no dilation against the normal pressure.

Wang and his colleagues conclude from this that there must be appreciable variations in the faulting process leading to shallow earthquakes. The degree to which V_p and V_s decrease will then depend on the extent to which faulting is associated with dilation and fracturing. The implication is that prediction based on precursory seismic wave velocity variations will not be possible even for all shallow earthquakes.

Antibodies to polynucleotides in SLE

from Graham R. V. Hughes

JUST under two decades ago, four groups reported almost simultaneously the presence of antibodies against DNA in the serum of patients with systemic lupus erythematosus (SLE). While early studies used double stranded (ds) DNA, it was found that many, if not all, SLE sera also reacted against single stranded (ss) DNA. Indeed it is now apparent that a heterogeneous collection of anti-DNA antibodies exists, binding to a variety of sites on the polynucleotides (Arana and Seligmann, *J. clin. Invest.*, **46**, 1867; 1967; Cohen, *et al.*, *Clin. exp. Immun.*, **8**, 551; 1971). During the past six years, the measurement of DNA antibodies by the ammonium sulphate precipitation technique (Farr) has become a standard clinical tool in the diagnosis and management of SLE. While antibodies against ds DNA occur almost exclusively in SLE, anti-ss DNA antibodies are not specific for this disease, occurring in rheumatoid arthritis, drug-induced lupus and a variety of other conditions, as well as in some normal sera.

The agent most commonly used in DNA binding tests is ^{14}C-labelled bacterial or mammalian double stranded DNA, and therein lies the main obstacle to standardisation of results. It has proved difficult using these preparations to assess the contribution to 'native' DNA binding of single stranded regions in the molecule. A recent study by Samaha and Irwin (*J. clin. Invest.*, **56**, 446; 1975) used a variety of techniques in an attempt to further characterise the antigenic regions in mammalian DNA. Using MAK chromatography followed by enzyme removal of single stranded regions, they showed that purified mammalian DNA is a mixture of almost homogeneous ds DNA, and ds DNA with significant single stranded regions. The latter were found to be rich in thymine, complementing the earlier studies of Koffler and his colleagues (*J. exp. Med.*, **134**, 294; 1971) who showed that sera with antibody to ds DNA are inhibited by the synthetic single stranded polymer poly(dA), less so by poly(dT), and least of all by poly(dC).

These studies suggest that some antibodies in SLE are directed at the ends of the molecule containing short thymine-rich single stranded portions and possibly also at areas of bifurcation between ds DNA and AT-rich single stranded regions in ds DNA. Thus it seems that the variable binding activity reported with various SLE sera may have more complex explanations, not simply reflecting specificity towards ss or ds nucleic acid, but possibly also pointing to differential binding of antibody to specific regions of structurally heterogeneous DNA. Two possible ways of bypassing the problem of ss DNA binding might be the use of circular ds DNA (such as SV40 DNA) or the use of synthetic self replicating polymers such as poly (dAT). Neither of these antigens has yet received adequate clinical trial. In the meantime, the clinical significance of slightly raised DNA binding values in some non-SLE sera remains uncertain.

Apart from clinical considerations, delineation of the various polynucleotide antigen–antibody systems has more than academic interest. The renal disease in SLE results largely from immune complex deposition, with DNA–anti-DNA antibody complexes being of considerable pathological importance. Less clear, however, is the relative contribution and possible interaction of the various polynucleotide complexes. Discrepancies appear to exist, for example, between the presence of anti-ss DNA antibodies in rheumatoid arthritis and scleroderma, and the lack of glomerular immune complex deposition in the majority of patients with these diseases.

One of the earlier known manifestations of circulating immune complexes in SLE was the presence of cold precipitating globulins (Christian, Haltfield and Chase, *J. clin. Invest.*, **42**, 823; 1975) and in a recent study, Winfield, Koffler and Kunkel (*J. clin. Invest.*, **56**, 563; 1975) have returned to cryoprecipitation in an attempt to determine the specific concentration of anti-polynucleotide antibodies in cryoprecipitates relative to serum levels. Using haemagglutination techniques, they found that antibody against ds DNA and ss DNA were both enriched up to a 100-fold in some SLE cryoprecipitates, as compared with serum. Antibody to ribonucleoprotein (thought to be associated with milder or absent renal disease) was only occasionally concentrated in cryoprecipitates. In contrast, anti-ds-RNA, which was commonly detectable in high titre in SLE serum, was only minimally concentrated, and only in a minority of precipitates. These data are in broad agreement with earlier elution studies of SLE glomeruli, where again anti-ds-RNA was not detected.

The findings again indicate that different anti-polynucleotide antibodies have differing pathogenetic properties. While this has, in essence, been known for over a decade, the dissection of these antigen–antibody systems appears now to be gaining momentum, the clinical goal being more precise management of SLE.

---

it may be necessary to use anti-inflammatory drugs during the early stages of treatment. In immune deficiency states there is a suggestion that uncontrolled lymphoid cell proliferation and autoimmune disease may be additional complications (Gelfand, E. W. *et al.*, *New Engl. J. Med.*, **289**, 1385; 1973, and Ballow, M. *et al.*, *J. Pediatr.*, **83**, 772; 1973). Lawrence (*Clin. Immunobiol., loc cit*) noted that "therapy with transfer factor (TF$_D$) as presently employed is empirical, since the precise mechanism via which this small molecule confers or uncovers a specific antigen–receptor site on the recipient's circulating lymphocytes remains to be clarified."

Immunotherapy with transfer factor for the persistent carrier of hepatitis B surface antigen or antigen carriers with chronic liver damage requires a cautious and carefully considered approach. The safety and effectiveness of such preparations should be evaluated as far as possible in animal model systems (*WHO Techn. Rep. Series*, No. 570, 1975). There is also, of course, a need to establish provisional standard reference preparations of transfer factor and studies on specificity are urgently required.

Carbon-13 NMR of proteins

from J. Feeney

IMPROVEMENTS in NMR instrumentation over the last few years have largely overcome the sensitivity problems which had previously retarded ^{13}C NMR studies of medium-sized molecules (molecular weight >1000). By using a combination of Fourier transform and proton noise decoupling techniques, high sensitivity natural abundance ^{13}C spectra can now be obtained for small peptides such as oxytocin, angiotensin and LHRH in which each carbon features as a single sharp resonance signal. For larger peptides there is considerable overlap of the ^{13}C spectral lines and when a small protein such as lysozyme is examined relatively few single ^{13}C resonances can be resolved.

Professor A. Allerhand and his coworkers (Oldfield *et al.*, *J. biol. Chem.*, **250**, 6381; 1975) have now reported methods which allow them to detect most of the aromatic quaternary carbons in small proteins. By using a proton noise decoupling field slightly off-resonance for optimum proton decoupling only the quaternary carbons are efficiently decoupled and the sharp signals from these carbons can then be separated from the very broad bands from proton-bearing carbons using convolution difference methods (Campbell, *et al.*, *J. Magn. Res.*, **11**, 172; 1973). The resulting spectra feature only the quaternary carbon signals. Allerhand and coworkers have applied these techniques to several native proteins (lysozymes, cytochromes *c* and myoglobins) and using concentrated aqueous solution (10–20 mM) in the 20 mm diameter sample tubes at 15.18 MHz they are able to obtain high quality spectra in ~5 h of accumulation time.

Many assignments of the signals could be made by consideration of chemical shifts, relaxation behaviour in H_2O and D_2O, selective proton decoupling experiments, *p*H dependence, deuterium isotope effects on chemical shifts and line broadening induced by bound lanthanide ions. For hen egg white lysozyme the γ-carbons of the 6 Trp residues have chemical shifts over a range of ~5 p.p.m.; when the protein is denatured with guanidine the signals coalesce into a single absorption band. In the ^{13}C spectrum of horse heart cyanoferricytochrome *c* all 18 non-protonated aromatic carbon signals are resolved. When the diamagnetic forms of haem proteins such as horse heart ferrocytochrome *c* are examined, the haem carbons are also detected in the spectra but these disappear in the spectra of the paramagnetic form. In mixtures of ferro- and ferricytochromes *c* there is fast electron transfer which produces exchange effects in the averaged spectrum such that a 1 : 1 correspondence between non-protonated aromatic carbon signals from the two forms can be established.

Clearly one can use the assigned ^{13}C signals in the various proteins to monitor protein unfolding, ionisation states of specific residues and interactions between the protein and other molecules. It should be borne in mind, however, that studies of ^{13}C at natural abundance (1.11%) have the disadvantage that they require large amounts (50 mM per sample) of soluble protein.

An alternative approach is to enrich the protein selectively with ^{13}C-labelled amino acids. In this way, the concentration and solubility requirements (<1 nm solutions can be examined) are reduced and a much wider range of proteins can be studied. Several workers have demonstrated that ^{13}C-labelled amino acids can be incorporated into bacterial proteins from auxotrophic organisms. An elegant example is found in the work of Hunkapiller and coworkers (*Biochemistry*, **12**, 4732; 1973) who isolated α-lytic protease from *Myxobacter* 495 grown on a medium containing all the naturally occurring amino acids including 2-^{13}C-labelled histidine. There is only a single histidine residue in α-lytic protease (His-57) and thus there is no assignment problem for the intense signal obtained in the protein ^{13}C spectrum. The C-2 carbon is coupled to the directly bonded proton and the measured $^1J_{CH}$ coupling constants are characteristic of the ionisation states of the imidazole ring ($^1J_{CH}$=219 Hz when the ring is protonated and $^1J_{CH}$=206 Hz for the unprotonated ring). Thus they were able to show from such measurements that the *p*K of His-57 is very low in the enzyme (*p*K <4), a fact which has important implications in understanding the mechanism of action of serine proteases.

Usually the incorporated labelled amino acid occurs at several different sites in the protein and one is faced with the difficult task of assigning the ^{13}C signals. A general solution to the problem of observing and assigning ^{13}C signals from proteins will be available when semisynthetic proteins can be made by incorporating synthetically prepared fragments containing several different labelled amino acids in a region of interest in the protein structure.

Tumour viruses discussed at Copenhagen

from Ian Macpherson

The Seventh International Symposium on Comparative Research on Leukaemia and Related Diseases was held in Copenhagen on October 13–18.

ONE of the most important issues raised at the meeting concerned the true nature of the C-type viruses apparently isolated from the leukocytes of a human case of acute myeloid leukaemia by Gallagher and Gallo (*Science*, **187**, 350; 1975) also from the bone marrow cells of a child with lymphosarcoma by Nooter *et al.* (*Nature*, **256**, 595; 1975) and from human embryo lung cells passaged in culture by Panem *et al.* (*Science*, **189**, 297; 1975). These viruses were recognised as typical C-type particles like those known to cause animal leukoses and were found to have antigenic and reverse transcriptase affinities with simian sarcoma virus (SiSV). These relationships were not considered to be surprising or even unexpected but what raised a few eyebrows at the meeting were the observations made in several laboratories using competition radio-immunoassay analysis and molecular hybridisation, that both Gallagher and Gallo's and Panem's isolates each contain two distinct viruses with uncomfortably close affinities to SiSV and the baboon endogenous virus At present it is not possible to say who got what from where and when. The forthcoming conference of the Virus Cancer Program at Hershey may help clarify these uncertainties.

Regardless of how these questions are answered there is evidence from other sources suggesting that man commonly encounters viruses antigenically related to the murine, feline and/or simian agents. H. W. Snyder (Sloan-Kettering, New York) found that most, if not all, adult human sera contain antibodies that combine with polypeptides from these C-type RNA tumour viruses. Placental cord sera are negative and sera from leukaemic patients reacted like normal sera. These results suggest that a virus or viruses with antigenic specificities common to the animal C-type viruses used as probes in this study are widespread in the human community. R. S. Metzgar (Duke University Medical School) reported antigenic relationship between RNA tumour viruses and surface antigens of leukaemic cells in cytotoxicity tests. He has shown that human leukaemic myeloblasts have antigens related to the p30 and gp70 proteins of Friend mouse leukaemia virus. R. A. Lerner (Scripps, La Jolla) has found that gp70 has a remarkable pleomorphism in the mouse. By immunofluorescence he has shown that this component of mouse leukaemia virus surface coat is also present in mouse lymphoid and epithelial cells and in the secretions of the epididymis. The system offers an excellent model for the study of host control of this gene's expression.

An interesting observation that may provide at least a partial explanation why C-type viruses are not as readily detectable in man compared with other animals also came from studies carried out at Scripp's: F. C. Jensen provided evidence that human complement, without the intervention of antibodies, was capable of lysing a wide range of C-type viruses. This may provide man with an important line of defence against infection with viruses of this type.

P. H. Duesberg (University of

California, Berkeley) described further progress his group has made on the mapping of avian tumour viruses. The 30–40S RNA, which they have shown to have a 3′ poly(A) end, was fragmented with alkali. Fragments with the poly(A) tag were separated according to size and the location of a particular oligonucleotide relative to the poly(A) end was deduced from the smallest piece that could be found. Different virus strains were found to share certain oligonucleotides and these were in approximately the same linear location. Comparisons between transformation defective, and virus envelope defective mutant viruses with their respective wild-type progenitors have shown that the transformation gene(s) (the *onc*) is located near the poly(A) end and that the information for the virus envelope (*env*) is nearby. The continued application of this type of analysis in the hands of such able interrogators should eventually provide a complete picture of the genetic map of these viruses.

Another intriguing probe into the avian sarcoma viruses and their dealings with the cell was described by D Stehelin (University of California Medical Center, San Francisco). By making a radioactive DNA complementary to the whole RNA genome of a transforming virus and "absorbing" it with the RNA of a mutant virus without the transforming functions they were able to make a cDNA *onc* gene probe. Leukosis viruses and transformation defective mutants lacked these sequences. Uninfected cells of a variety of avian species including duck (which so far has not been found to contain an endogenous virus) contain the nucleotide sequences of the probe in their DNA but do not transcribe the gene into RNA. However, their finding that methylcholanthrene induced tumour cells from the quail contained homologous RNA to their probe is of considerable interest and hints at a link between chemical induction of tumours and the activation of "viral" genes.

The small DNA tumour viruses were brought back into the arena by H. zur Hausen (Universität Erlangen-Nürnberg). He has shown that human genital and laryngeal warts which sometimes undergo malignant transition were not found to have any measurable homology with a complementary RNA prepared from plantar wart DNA. This suggests that there are a variety of papilloma viruses in man, some of which may be responsible for malignant tumours This field may be due for a revival especially since there has been a recent report by Eisinger *et al.* (*Nature*, **256**, 432; 1975) that human wart virus can be grown in tissue culture. □

Cell motility moves ahead

from E. W. Taylor

The most recent conference in the Cold Spring Harbor series on Cell Proliferation, entitled Cell Motility, was held on September 9–14.

A KNOWLEDGE of how cells move and how their movements are controlled is necessary for an understanding of a variety of biological processes including embryological development, the wiring of the nervous system, and the invasive transformation of the cancer cell. During the past few years the number of papers devoted to some aspect of cell motility has increased enormously. The conference was a largely successful effort to establish communication among the practitioners in this diverse field The topics included muscle contraction, non-muscle actomyosin and streaming, structure and function of animal and bacterial flagella, chemistry and assembly of microtubules and mechanisms of mitosis.

Three main classes of motile systems can be distinguished on the bases of protein composition and energy transduction mechanism, the bacterial flagellum.. the eukaryote flagellum, the actomyosin system of muscles and cytoplasmic streaming.

The mechanism of bacterial flagella movement has long been a puzzle since the flagellum consists of a single protein with no known enzymatic activity. It has been shown that the flagellum does not propagate helical waves but rotates, driven at the base by a structure in the membrane. The sense of rotation can be reversed, producing swimming in the opposite direction if a single flagellum is present or preventing swimming by untwisting the flagella bundle. A physical analysis of the motion was presented by H C. Berg (University of Colorado) and the experiments establishing the rotation mechanism and the properties of motility mutants were discussed by M. Simon (University of California, San Diego) and J. Adler (University of Wisconsin). D. E. Koshland (University of California, Berkeley) described elegant mixing experiments which established the point that the chemotactic response was elicited by a change in concentration with time rather than a spatial concentration gradient across the bacterium. These studies lead to a simple model of chemotaxis which should be widely applicable to the movements of animal cells. The frequency of reversal of the motor is reduced by an increase in concentration of attractant. In simplest terms, if a bacterium is moving up a concentration gradient, motion in this direction will persist longer. If it moves down the gradient it will stop in a shorter period of time and try a new direction. As a result the step lengths in a random walk are biased in the direction of the concentration gradient.

The sliding filament–swinging cross bridge mechanism of muscle contraction has been firmly established and a reasonable correlation has been made with corresponding biochemical events in ATP hydrolysis by actomyosin. In recent years actomyosin has been isolated from a variety of tissues and organisms (brain, platelets and fibroblasts of vertebrates, slime mould, amoebae and algae). It is very likely that actomyosin is responsible for cytoplasmic flow and actomyosin-containing extracts of amoebae, studied by D. L. Taylor (Harvard University), mimic the flow properties of the intact cell. Several laboratories have studied the properties of cellular actin and myosin and a pattern is beginning to emerge. While the actin and myosin are similar to but distinguishable from their muscle counterparts, the regulation of ATPase activity and aggregation into gels depends on factors which are different or absent from the muscle system. Preliminary characterisation of protein factors which regulate actin polymerisation, aggregation of actin into bundles and formation of gels has been achieved in slime moulds by S. Hatano (Nagoya University), M. R. Adelman (Duke University Medical Center), J. A. Spudich (University of California, San Francisco), in amoeba by T. Pollard (Harvard Medical School) and in macrophages by T. P. Stossel (Children's Hospital Medical Center, Boston). Regulation of ATPase activity by Ca requires a protein factor which is distinctly different from troponin or a myosin light chain. Recent studies on this factor in amoeba and macrophages were reported by Pollard and Stossel respectively The field has passed out of the stage of counting up the number of systems which contain actomyosin to go on to the determination of the special properties of actomyosin systems which are peculiar to cytoplasmic flow.

Bundles of actin filaments are common cellular components but under some conditions a lattice is formed with α-actinin (a muscle protein) anchoring the crossover points of the lattice. Fluorescent antibody staining developed by E. Lazarides (Cold Spring Harbor) has enabled these complex networks to be made visible. At present we are suffering from a surfeit of actin filament bundles which seem to be present even in the mitotic spindle. These studies have reopened the question of whether actomyosin participates in chromosome movements (the question was not settled). The possibilities of artefacts in preparing cells for antibody or heavy meromyosin (HMM) labelling was keenly discussed and although there is growing evidence for the presence of actin, myosin has not been demonstrated. The studies of L. G. Tilney (University of Pennsylvania) have shown that actin is present on its own in the acrosome bodies of sperm from a variety of species and is driven into the egg by polymerisation or uncoiling. Thus the presence of actin in a cell organelle need not imply the presence of myosin as well.

Some three years ago, R. C. Weisenberg (Temple University, Philadelphia) developed a method of polymerisation of tubulin into microtubules. This work stimulated an intense study of the mechanism of microtubule polymerisation and the search for microtubule organising centres. Condensation of tubulin into outer doublets of flagella and asters of the mitotic apparatus has already been described and evidence was presented (by two different laboratories) for the chromosome kinetochore as an organiser. Microtubule polymerisation has turned out to be a complex process, more like virus assembly than the type of spontaneus polymerisation that occurs with fibrous proteins (actin for example). The formation of a ring structure by a protein factor or possibly polyvalent ions, the use of the ring as a nucleating centre, the participation of high molecular weight factors, and enzymes (transphosphorylase and possibly a protein kinase), the requirement for nucleotide triphosphate hydrolysis, as well as three different polymerisation models (H. P. Erickson–M. Kirschner (Duke University), G. G. Borisy (University of Wisconsin), M. Jacobs *et al.* (King's College, London)) were discussed. While it is clear that rapid progress is being made on this problem, more rigorous purification of the system is necessary before the discrepancies between different groups can be resolved. ☐

Transient observations of X-ray sources

from John Gribbin

At the Royal Astronomical Society meeting on October 10 the nature of the transient X-ray source Ariel 0620-00 was discussed.

THE discovery of the source early in August was described by M. Turner (University of Leicester). There was a rapid rise in intensity, with one slight hiccup, which made A0620-00 three times brighter than Sco X-1 by the middle of the month (see *Nature*, **257**, 656, 657; 1975). The hiccup, or 'precursor peak' seems to have marked a change in the energy production mechanism, with a fall in temperature preceeding the most rapid period of increasing brightness, and with the bulk of the increase occurring at low energy (below 10 keV) making this a very soft source. No lines have been found in the spectrum, although searches have been made especially at frequencies appropriate for ionised silicon and sulphur, and there is no evidence of polarisation at what Turner described as "the lowest upper limit yet achieved in X-ray astronomy" and there is no evidence of periodic variations anywhere in the range 0.2 ms to 2 d.

But there are some positive interpretations of the X-ray evidence, not least a SAS 3 measurement of the hydrogen column density to the source which implies a distance of 3 kpc if all absorption is interstellar, suggesting an absolute luminosity of 10^{39} erg s^{-1}.

A0620-00 has also been detected at radiofrequencies and identified with an optical star (see *Nature*, **257**, 659; 1975). R. Davis (Jodrell Bank) described radio observations both at Manchester and elsewhere which help to provide a very accurate position in right ascension, although the declination is less well determined because of the inconvenient position of the object for such measurements. The source is variable, and declined from peak intensity after August 18 with an *e*-folding time of 5 d, considerably faster than the equivalent X-ray decline (1/*e* fall off over 30 d). Assuming the outburst began on August 3, the radio data can be fitted by a T^{-3} power low.

The optical observations were described by M. Penston (Royal Greenwich Observatory), who preferred to call the event Nova Monoceros 1975 but agreed that he was indeed talking about the same thing. There seems no doubt at all about the identification of the optical and X-ray novae, and comparison with Palomar Sky Survey plates shows that during the outburst the source increased from a magnitude of 20.5 to 11.5, a brightening which is on the high side for dwarf novae but not unprecedented. The Palomar plates also show that the star was very red before the outburst, suggesting that it may be a red dwarf only some 500 pc away or a giant at the implausible distance of 15 kpc which, in the direction of Monoceros, would place it not only well out of the Galaxy but far above the galactic plane. At optical frequencies, the fade of the source has been little slower than in the X-ray band but faster than at radio frequencies, indicated by measurements up to a few days before the RAS meeting.

For the modellers, one of the most significant contributions comes from a search of Harvard plates which show a previous outburst in 1971, reaching 12 mag. This strongly implies the presence of circumstellar material leftover from that event, suggesting that the SAS 3 distance must be an upper limit and pinning the object down clearly as a red dwarf probably closer than 1 kpc.

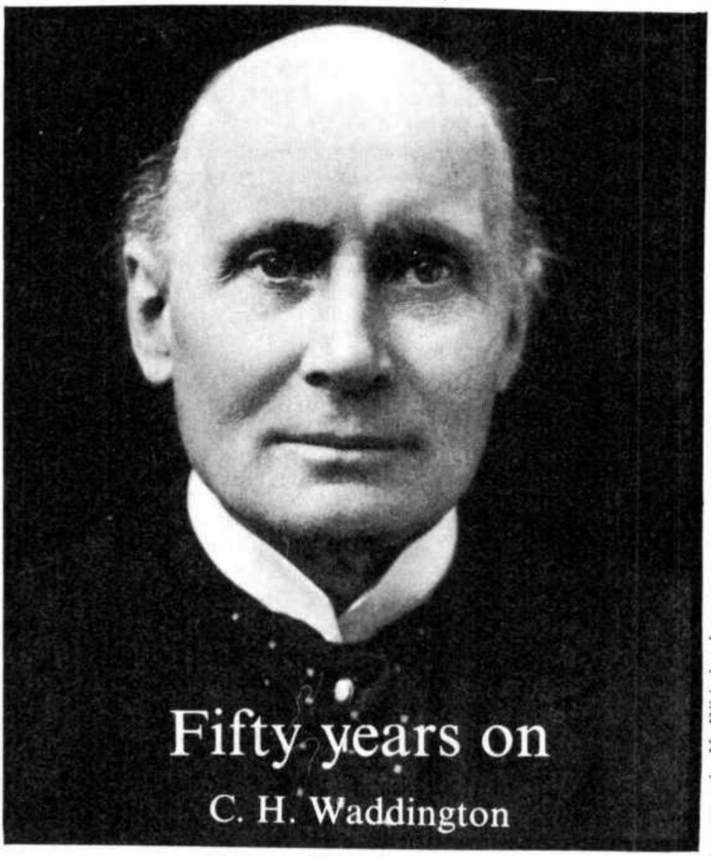
A. Fabian (Institute of Astronomy, Cambridge) took up this theme in presenting a model of A0620-00. Pointing out that this is the first optical identification of a transient X-ray source, he made a leap which perplexed some optical astronomers—but not the X-ray specialists—by assuming the now basic model of a binary source with mass transfer from the visible star onto a compact companion, probably a neutron star. The probability of seeing an eclipse on such a model is only 12%, so it is not surprising that none is seen in this source, and the increase in brightness of the dwarf is caused by the heating effect of X-radiation from the companion on one face of the larger star. The fact that novae seem to recur in this system encouraged Fabian to make a comparison with the recurrent nova WZ Sge, itself a similar binary system, and although this detailed model is unlikely to fit all the transient X-ray sources it is interesting that a very similar model has already been proposed for the archetypal X-ray source Sco X-1, again drawing a comparison with WZ Sge.

This raises the question of just how different the transient X-ray sources are from the rest of the family. All of the known X-ray sources that are not supernova remnants show very erratic behaviour with flares and quieter periods, and if Sco X-1 can be explained, after more than 10 years observation, by a model similar to that appropriate for a newly discovered source which flared into prominence for only a few weeks it seems that the differences may well be of degree rather than of kind. The observations themselves are far from continuous, and the label hung upon any particular source can depend to a large extent on the state it happened to be in when it was first noticed. Perhaps the main lesson to be learned from the story of A0620-00 so far is that all X-ray binaries are variable, but some vary more than others, and that rather than talking about "observations of transient X-ray sources" we would do better to talk about "transient observations of X-ray sources". ☐

Michael Shillaker

Fifty years on

C. H. Waddington



A. N. Whitehead

WHEN asked to write on the books that scientists were reading when I was young, I thought at first that it would be impossible to make anything of interest out of what I personally had been reading. There are, however, some points which may have some wider relevance. We will be dealing with the years 1925–30, when I was 20 to 25. That was just before many things happened, which we now accept as in the very nature of things.

When I ask myself "what was that time *before*?", I have to think of a very wide range of different topics. At that time it seemed absolutely natural that a young man of my age, interested as all such people are, in the nature of the world in which he was beginning to find his feet, should expect to find out about a great many different aspects of it. Not only his own science, but several sciences connected with it, even if only loosely. My 'official' interest was in what fossils can tell us about the processes of evolution. There was not very much general reading in that connection. That was *before* the development of mathematical neo-Darwinism, although J. B. S. Haldane was beginning to do some elementary sums about the selection of single genes, which he, rather sensibly, treated rather as undergraduate *jeux d'esprits* than as the profound contributions to fundamental biology which people later—and still—pretended them to be.

It was also absolutely natural to have interests in philosophy, poetry, even painting, and to allow them to show. This was well *before* there was considered to be any firm dividing line between the natural or the moral sciences, or even between those and the arts. It is in these areas that some of the *befores* are most difficult to clarify. Eliot's *The Waste Land*, and some of Ezra Pound had already been published, but it was *before* their influence had changed the whole direction of English poetic taste, at least as far as I was concerned; at that time, I was still reading English poets of the generation of Wilfred Owen, Edward Thomas, Gordon Bottomley, Walter de la Mare, the Sitwells and the American experimentalists and imagists, such as e e cummings, Laura Riding, Hart Crane, John Crowe Ransom and H.D.

But most important of all, certainly for my future development, were books by two people who were closely associated and who brought literary criticism and philosophy very near together. The official philosophers in Cambridge, such people as Broad and Moore, had already some of that remoteness which later became almost the hallmark of the profession. But this was *before* the influx of that remarkable succession of Viennese intellectuals which have dominated British philosophy since the early thirties—Wittgenstein, the first, best, and only one to recognise for himself that he had been talking nonsense and to spend the rest of his life unsuccessfully trying to get it right; followed by Schlick and Karnap, with their first major British follower, Ayer; then Popper, and Lakatos and now Feyerabend, whose book, *Against Method* (NLB London, 1975), should be the expiring gasp of the lineage of thinkers who set out to describe the definitive method of science in terms of logical algebra.

The two people I refer to, just *before* these, were I. A. Richards, with his *Principles of Literary Criticism* followed a few years later by *Practical Criticism*, and C. K. Ogden, who collaborated with Richards in *The Meaning of Meaning*, which was much more philosophy than criticism. Ogden also introduced us to, at least some, of the problems of linguistics, first from his own viewpoint, by the attempt to develop a "minimum effective language" (Basic English), but later using the fashionable Viennese ideas, as the first translator of Wittgenstein's *Tractatus*. I doubt if, today, you would find anywhere the intimate interplay between poetry, philosophy and the foundations of science which Ogden and Richards displayed.

The other main influence on me as a young man just growing up as a scientist, was that of the philosopher, A. N. Whitehead, the writings of whom some younger biologists seem to associate with molecular biology, or the even more recent influences of Levi-

Straus and Chomsky. He was the senior author, with Bertrand Russell, of the great tome on *Principia Mathematica* which laid the foundations of philosophy in the mode of logical algebra. His later treatment seems to me to border on the fantastic. It was Russell who persisted in the directions adumbrated in the *Principia*, and that work seems nowadays to be considered virtually his alone. In fact, Whitehead scarcely gets mentioned in most modern outlines of philosophy except as Russell's co-author in that work.

Admittedly, Whitehead did not make it easy for readers of later generations who were in a hurry to catch up. For instance, R. F. Atkinson (Twentieth *Century Mind*, **2**, Oxford), dealing with British Philosophy, from 1918–45, finds little more to say than: "His major metaphysical works are *Science and the Modern World* (1925), *Adventures of Ideas* (1933), *Process and Reality* (1929)—the latter very difficult work being the most complete statement of his views—...and a vast expenditure of time is needed to come to terms with his system. His opponents therefore ignore him instead of criticising him in detail". This is as though some one felt he was duty bound to assess the literary worth of James Joyce, and decided, after plunging into *Finnegan's Wake* for half an hour, that Joyce was not worth bothering about.

One should approach *Finnegan's Wake* through *The Artist as a Young Man* and *Ulysses;* one should approach *Process and Reality* through *The Principles of Natural Knowledge, Symbolism, its Meaning and Effect* and others of Whitehead's earlier writings, including *Science and the Modern World* (recognising that, however, as being something of a popularisation). Although I took this course in both cases, I confess I never quite made the grade to a confident mastery of either of the two *magna opera*—both a bit too big for their boots. I will go along with Atkinson that he is a difficult author, but that is more because his ideas are unfashionable and profound than on account of his readiness to redefine words to suit his own purpose.

Whitehead totally inoculated me against the present epidemic intellectual disease, which causes people to argue that the reality of anything is proportional to the precision with which it can be defined in molecular or atomic terms. Whitehead's main thoughts were *before* quantum mechanics; his refusal to grant prior validity to matter or atoms was not so much because no one knows what they are, but rather because all our knowledge has its roots in experience. Science is not based on physical or material realities, it is based on experiments. An experience is something more immediate than the distinction we are immediately tempted to make within it, into the objective and the subjective; it contains both of them.

Whitehead's major thesis was the rejection of what he called "The Bifurcation of Nature", into Mind and Matter, set against one another as two totally separable and incomparable essences. Of course it is often convenient to work with a rough and ready distinction for particular purposes. But he was—and I am—totally opposed to an unbridgeable gap between them—the "Cartesian Dualism", the "Naturalistic Fallacy", and all the rest of the rigmarole which is bringing science into such disrepute with the open-minded younger generation of today. If I had started reading philosophy a few years later, Whitehead would already have been pushed out of fashion by Wittgenstein and Russell, and I would probably have failed to grasp this point. ☐

Professor Waddington died shortly after completing this essay. An obituary will appear in a later issue.

Festschrift

Arthur Koestler. Photo: Michael Brett

Astride the Two Cultures: Arthur Koestler at 70. Edited by Harold Harris. Pp. 219. (Hutchinson: London, 1975.) £5.50.

I do not see how it can help but look singularly graceless to take up a critical stance towards *Astride The Two Cultures*, a *Festschrift* for Arthur Koestler on his seventieth birthday. Graceless or not, I have to disclose immediate disappointment at not finding a contribution originating in what I nowadays call the hard-core sciences, those grouped round mathematics and physics.

When C. P. Snow coined the phrase "The Two Cultures", it was clearly the hard-core sciences which he saw at the one pole; and Mr Koestler in his own writings handles some of the concepts of theoretical physics. The contribution coming nearest is by W. H. Thorpe, the distinguished animal ethologist: he deals with Mr Koestler's views on reductionism and with his ideas about the hierarchical nature of 'living organisation', making use in his frame of reference of the philosophies of Karl Popper and Jacques Monod—good hard-core thinking. Naturally Professor Thorpe is not the only writer to notice the parallel between Mr Koestler's ideas about hierarchy and General Systems Theory. (Briefly: Mr Koestler remarks that an element of a living organisation seen from one point of view appears as a non-autonomous part of the whole, but from another point of view as an autonomous individual.) As a literary metaphor it's nice, and falls in with non-deterministic principles, but it suffers from the limitations of literary metaphor. Theoretical physics may be called a mathematical metaphor: the difference is that mathematical metaphor enables you to penetrate to deeper levels of physical understanding, whereas literary metaphor only enhances your view on one level. As with Bohr's statement of Complementarity—it's nice, the more you look around you the more examples you see: but how much further forward does it get you? Thus, but more so, with Mr Koestler's "Janus-faced holons".

Under the current English dispensation you're expected to address yourself, in contributing to a Festschrift, to the work of the person being celebrated: under the original German dispensation you get away with printing large slabs of your own work—three of the present social scientist contributors operate on original German lines. One improves the shining hour with polemic against one of his academic colleagues—yes, Academe is located in the provinces. Another provides a large slab about personality traits: I'm sure diagnosing and assessing personality traits finds honest work for psychologists; it's bad luck that the upshot happens to be lifeless. A third studies animal behaviour: often I strongly deplore this kind of study, because it carries a *sub rosa* message of excuse for us human beings doing what the animals do. In this contribution the animal is a species of monkey whose males impress each other by exhibiting their phalli: if there's the *sub rosa* message here, it would seem to me harmless, in fact favourable to the spread of general merriment.

Atop the other pole—the idiom of the title is catching—sits Goronwy Rees with an excellent appraisal of *Darkness At Noon*. I've never been able to understand why first becoming a Communist and then becoming an anti-Communist should attract a special kind of moral credit such as is not accorded to someone who has had the sense to do neither. Performing two intellectual U-turns may purify a man's spiritual nature, but it doesn't establish him in my opinion as a reliable thinker. What it may do, it seems, is provide him with material for art. Generally speaking the question "Does the end justify the means?" is most suited to a College Debating Society, the answer being given by a count of Ayes and Noes. Mr Koestler, as Mr Rees demonstrates, has transformed an examination of the question into a work of art. I should have thought Mr Koestler's argument was skewed intellectually by the pressure of abnormally strong feelings of guilt—you really can't get to the truth when there's so much guilt about the place—yet as a work of art the book is clearly a classic. But I do feel bound to look back again to the opposite pole, where I find it hard to go along with the claims made for Mr Koestler there. He is extremely clever and he knows what some of the concepts of the hard-core sciences are about: I take leave to question very seriously the uses to which he puts them.

Of recent years Mr Koestler has become increasingly preoccupied with the so-called 'para-' subjects—telepathy, telekinesis, parapsychology and so on. In writing for *Nature* about Aldous Huxley, who also came to have this preoccupation, I lumped them all together under the title 'parascience', where 'para-' according to the Oxford English Dictionary meant 'beyond, wrong, irregular' and according to me could be replaced by 'non-'—'non-' being at only one stage before 'anti-'. In *The Roots of Coincidence* Mr Koestler begins by trying to establish parascience on the same footing as science: by saying that theoretical physics breaks previously sacrosanct 'laws of nature' in for instance the concepts of negative mass and time reversal, while parapsychological research has become more rigorous, statistical, computerised. A specious argument: on the one hand negative mass and time reversal are straightforwardly within the logic of the established mathematical metaphor; whereas everybody knows you can be rigorous, statistical, computerised from premisses that are entirely fallacious. Mr Koestler then goes on to postulate a world of psychic reality alternative to that of physical reality (and interwoven with it in the matrix of 'oceanic reality'; complementarity is invoked, of course), where the seemingly acausal events of the paraworld—amazing coincidences, peculiar premonitions, levitating tables and crumpling spoons—may be as accounted-for as the casual events of the physical. The world of 'oceanic reality' you reach by way of mystical or mescalin experiences.

One can readily take a magnanimous line towards Mr Koestler as a man. For instance when he flirts in *The Midwife Toad* with Lamarckism, one can see his sense of justice compelling him to establish the claims of dissident off-beat minds in the dialectical process of arriving at scientific truth. And when he attacks determinism one can only respect that element of the human spirit which insists on having some say in its own fate, and which rejects the idea of absolute predetermination and inevitability. But one's attitude to him as a thinker has to be cautious, clever as paint though he may be. One has to watch out for preoccupation with the paranormal turning a man into a parathinker. **William Cooper**

Chromatographic

Extraction Chromatography. (*Journal of Chromatography* Library, Volume 2.) Edited by T. Braun and G. Ghersini. Pp. xvii+566. (Elsevier Scientific: Amsterdam, London and New York, 1975.) Dfl. 130; $54.25.

THE title of this book will be unfamiliar to most western practitioners of chromatographic separation methods. It is defined in chapter 1 as the reversed-phase partition chromatographic separation of ions usually, although not necessarily, using systems which greatly favour partition into the stationary phase. Various means, including complexing and chelating agents as well as physical partition, are used to achieve this end. The separations described in this book are exclusively inorganic, although this does not seem to be intrinsic in the method.

I personally feel that this nomenclature is unfortunate in that it does not give due emphasis to the distribution between two phases, which is the essential mechanism of all chromatographic processes. It has arisen, however, from the extensive use of liquid–liquid extraction in the separation of the products of nuclear fission, the chromatographic applications having followed later. In so far as the term extraction chromatography is restricted to those inorganic chromatographic separations, in which an ion is converted into a non-ionic complex which is extracted preferentially into a non-aqueous stationary phase; it is probably an acceptable innovation.

Within these limits this collaborative work succeeds admirably. After introductory chapters on the theoretical aspects and the correlation between chromatographic and liquid–liquid partition results, three excellent chapters describe experimental methods (which are necessarily rather elaborate in all reversed-phase partition chromatographic techniques), stationary phases (in considerable detail) and support phases. The last by Katykhin is outstanding and will be very valuable to organic chemists and biochemists as well as those concerned exclusively with inorganic separations. This chapter contains a wealth of tabulated material on all the commonly used support phases, including physical properties such as density, surface area, total porosity, average pore diameter, capacity for typical organic stationary phases and HETP values for a wide range of chromatographic systems. International suppliers, including those in east European countries, are also tabulated. To my knowledge no such extensive compilation has appeared elsewhere. Katykhin also discusses the pretreatment of the support materials and column packing. He also includes a description of the preparation of sintered porous PTFE blocks which can be moulded into any required shape, and can be used repeatedly in a variety of reversed-phase chromatographic systems, including annular blocks for continuous chromatography.

The remainder of the book deals with special applications of extraction chromatography to specific inorganic ionic groups. Stronski deals with the separation of radionuclides, and shows that in the majority of cases a difference of unity in atomic number suffices for complete separation. Separations of the individual elements are also usually possible in most vertical columns of the periodic table, for example, Li, Na, K, Rb and Cs; Ca, Sr and Ba; Au, Pt and Pd; and the halides, F, Cl, Br and I. Complete separations in the IVth, Vth and VIth groups, however, are still difficult. Separations of the actinides and lanthanide elements are described in chapters by Muller and Siekierski.

In summary it seems that good separations of most pairs of inorganic ions can now be achieved simply and effectively by extraction chromatography both on the analytical and preparative scales. The method is particularly suitable for highly radioactive elements, as preparative separations can readily be carried out by simple remote control in well-shielded enclosures, whereas analytical separations can be carried out at such high dilutions that special precautions are usually unnecessary.

This book provides an excellent and complete coverage of the whole field of the separation of inorganic ions by column, thin-layer and paper chromatographic methods, and as such it is highly recommended.

C. J. O. R. Morris

Insect miscellany

Insects, Science and Society. (Proceedings of a Symposium held at Cornell University, Ithaca, New York, October 14–15, 1974.) Edited by David Pimentel. (Academic: New York and London, July 1975.) $15; £7.20.

THE symposium on which this book is based was held in Cornell University in October 1974 to celebrate the centenary of the teaching of entomology at Cornell—indeed, in the United States—coupled with the name of the founding father John Henry Comstock, who gave the first course of lectures while still an undergraduate. The well known achievements of Comstock are briefly reviewed by E. H. Smith. D. Pimentel gives a general introduction on insects and crop production in the US, and J. J. McKelvey a colourful picture of 'insects and man'. E. O. Wilson contributes a brilliant short essay on the evolution of insect societies, in which their potential for studying the nature of sociality is stressed.

R. D. Alexander gives a lengthy account of chorussing behaviour in Orthoptera and cicadas, which is largely a re-interpretation of the author's earlier observations, the stress now being laid on the selective advantage secured by individual males in the competitive search for a mate, rather than on the advantage for the group. W. L. Roelofs reviews his own researches on the red-banded tortrix (leafroller) as an example of the physiological properties of pheromones and of their potential use in monitoring populations and perhaps in control by trapping or mating disruption. In a stimulating essay J. S. Kennedy argues persuasively for the view that all migration (and that includes 'dispersal') in insects involves a behavioural response, an essential component of which is the suppression of reproductive ('vegetative') activity and its temporary substitution by active locomotion, with or without passive transport by the elements. M. D. Pathak reviews the methods and results of plant breeding for resistance to insect pests as illustrated by the wide ranging studies on rice.

According to a valuable contribution by T. R. E. Southwood the competing models of population dynamics at varying densities all contain elements of the truth, and that an approximation to real life can be obtained by integrating these models into a single framework which also takes account of habitat stability. As P. S. Messenger points out in a paper on parasites, predators and population dynamics in California, that even in highly developed monocultures the complex of insect species is very large and general predators are a major element in integrated control schemes. W. Klassen gives an account of the planning and administration of the insect control programmes as organised by the US Department of Agriculture, in which it is claimed that increasing stress is being placed on 'integrated control'.

The final article, by L. D. Newsom, deals with 'pest management' (synonymous with integrated control)—the standard procedure of the entomologists of the nineteenth century, which he illustrates vividly in relation to cotton and soya bean culture in the US. There seems little doubt that the future lies with these ecological procedures. But they require skilled and imaginative entomologists; they are vigorously opposed by the salesmen of the chemical industry whose approach appeals more to the grower; and they still lack administrative encouragement. They do, however, have some enthusiasts on their side.

Although not closely integrated, and although reproduced in offset typescript, this book contains a high proportion of valuable articles.

V. B. Wigglesworth

Stellar essays

Problems in Stellar Atmospheres and Envelopes. Edited by B. Baschek, W. H. Kegel and G. Traving. Pp. xix+375. (Springer: Berlin and New York, 1974.) DM48; $20.70.

THE occasion of the seventieth birthday of one of the world's most distinguished authorities on the theory of stellar atmospheres and the quantitative analysis of spectral lines—Professor Albrecht Unsöld of Kiel University—has been marked by the production of this *Festschrift* to which eleven of his former pupils have contributed review articles on stellar atmospheres and related topics, expressing at the same time the hope that others will find them interesting and stimulating.

This hope is certainly fulfilled by the great majority of the articles, in which the authors give their personal viewpoint on several topics of current interest in stellar astrophysics. Classical problems relating to the structure of stellar atmospheres are discussed by D. Labs, who gives a convincing defence of the solar irradiance tables published by Labs and Neckel in 1968 and 1970, and by Mrs E. Böhm-Vitense who uses a grid of model stellar atmospheres in radiative and local thermodynamic equilibrium to predict continuous spectra and colour indices as a function of temperature, luminosity and chemical composition. From a less classical point of view, G. Traving discusses the formation of spectral lines in turbulent media and the physical significance of the controversial empirical parameter known as "microturbulence". Moving out from "atmospheres" to "envelopes", W. H. Kegel describes the theory of maser action in OH and H_2O emission sources, while L. Oster gives a rather entertaining historical review of radio emission from stars and its significance —a subject that has been close to Unsöld's heart since the 1950s— and K. H. Böhm describes physical conditions in the rather mysterious Herbig–Haro objects and in the related nebulae surrounding T Tauri stars, which may result from shock-heating by the impact of a stellar wind on the intracloud medium.

The remaining articles concern the application of stellar atmosphere theory to abundances of elements and other problems in stellar internal structure and evolution. K. Hunger discusses the helium stars, concluding that some of the intermediate variety (as well as the extreme ones) achieve this state by nuclear evolution, whereas others may be affected by atmospheric diffusion. Further abundance anomalies in hot stars (mainly with weak helium lines) are lucidly described by B. Baschek, together with the many mechanisms that have been proposed to account for them, among which the diffusion hypothesis of G. Michaud is generally the most successful, although other mechanisms may also be involved. Diffusion is also clearly important in white dwarfs, which are discussed in a useful review by V. Weidemann that covers their role in galactic evolution as well as their atmospheric properties. K. Kodaira describes the spectral analysis of A-type horizontal-branch stars which is of interest both as a source of information on the chemical composition of old objects and as a means of determining the mass–luminosity ratio, which can then be compared with predictions from evolution and pulsation theories; and D. Reimers discusses the rate of mass loss from red giants on the basis of circumstellar absorption-line observations, deriving an empirical formula which shows that observed mass-loss rates are sufficient to satisfy evolutionary requirements for stars having less than twice the mass of the Sun.

Altogether this book is a worthy tribute to its illustrious dedicatee and a welcome addition to the astronomical review literature.

Bernard Pagel

Imaginative reflections

The Lives of a Cell: Notes of a Biology Watcher. By Lewis Thomas. Pp. 153. (Viking: New York; Garnstone; London, November 1975.) $6.95; £3.50.

FOR once the publisher's blurb is correct; this is an extraordinary book. At first glance this is not apparent. The book is a collection of essays, 29 of them, each no more than about five pages long, reprinted from issues of the *New England Journal of Medicine* from 1971 to 1973. The author is a distinguished clinician, but the essays are not about medicine (except incidentally); most of them are imaginative reflections about societies of insects and men. The best way to convey the flavour of Thomas' book is to say that he looks with wonder and understanding at the behaviour of some simple organisms—in which he includes mitochondria, chloroplasts, bacteria, ants and termites—and his wonder leads him to speculate about the behaviour of man. This theme could be a recipe for sentimental teleology—a sort of latter-day Maeterlinck. But Dr Thomas is too good a biologist to fall into that trap. He knows that to impute even the rudiments of human intelligence to insect communities is nonsense; social insects have no choice but to build nests or hives, to store food, to cultivate fungi, to live in symbiosis with other creatures; all under inflexible genetic compulsion. But (he asks) are there not also examples of genetically coded behaviour in men and communities of men? And it is his speculations about this question which make this book such delightful reading. I use the word 'delightful' deliberately; for the book contains few facts which are not familiar to biologists, and it does not weave these facts into logic, it spins speculations out of them. The essays are little flights of imagination, written with charm and wit. But they are anything but trivial. In practically every essay something familiar is suddenly put into a fresh light, and it looks quite different; and this, of course, is precisely how creative science is achieved. Dr Thomas has a flair for 'thinking otherwise' about familiar things.

For example, he includes mitochondria as 'organisms', for one of his themes is the prevalence of symbiosis in the whole spectrum of nature from termites to men. Mitochondria, he explains, "replicate in their own fashion, privately, with their own DNA and RNA quite different from ours." They are "stable and responsible lodgers" in the human body. Symbiosis is a symbol of the interdependence of living things, part of the process which constructed metazoans from single cells, communities from metazoans, and ecosystems from communities. He calls as witness the symbiotic service which the protozoan *Myxotricha paradoxa* gives to the termite community, providing the enzyme to break down cellulose.

Another theme of these essays starts with the question asked two generations ago by W. M. Wheeler: "To what extent can insect communities be regarded as organisms?" (It was Hegel who asked a homologous question about the State.) A familiar enough idea, but Dr Thomas illuminates it from a fresh direction:

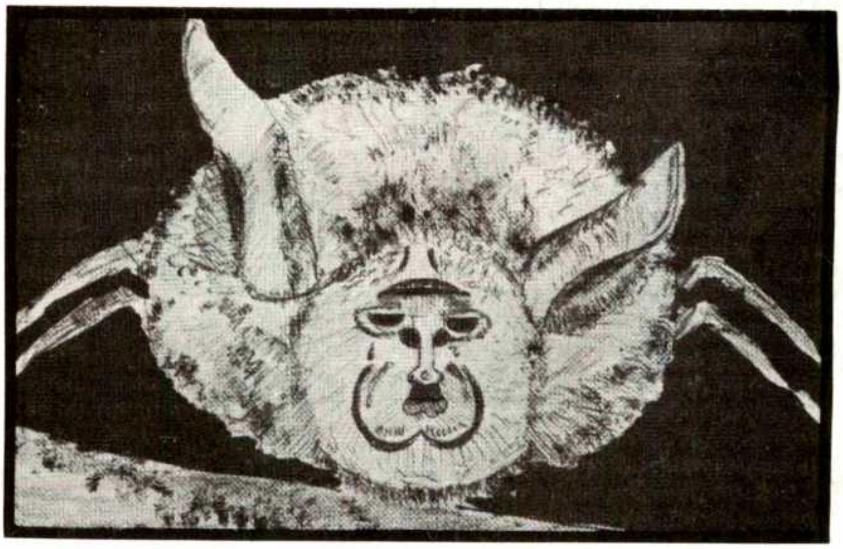
> "Viewed from a suitable height, the aggregating clusters of medical scientists in the bright sunlight . . . at Atlantic City, swarmed there from everywhere for the annual meetings, have the look of assemblages of social insects. There is the same vibrating, ionic movement . . . the darting back and forth of jerky individuals to touch antennae and exchange small bits of information . . ."

And what are the scientists doing? They "are linked in circuits for the storage, processing, and retrieval of information." What societies of termites do with cellulose, societies of men do with information, rearranging it against randomness into such patterns as quantum mechanics, immunology, genetics. And so Dr Thomas sees an analogy between the termite team (ineffective unless there is a quorum of termites), building something beyond the conception of any of the individual builders, and the invisible college of scientists, piecing together fragments of information into ordered patterns of understanding. There even seems to a similar compulsion:

> "Scientists at work have the look of creatures following genetic instructions; they seem to be under the influence of a deeply placed human instinct. They are, despite their efforts at dignity, rather like young animals engaged in savage play."

As a solution appears they become agitated, as bees do in a disturbed hive, and there "suddenly emerges, with the purity of a slow phrase of music, a single new piece of truth about nature."

Fanciful? Yes, it is; but it is this sort of fancy which acts as a catalyst for hard science. As A. N. Whitehead wrote: "It is more important that a proposition be interesting than that it be true." And Dr Thomas' theme is intensely interesting, for he goes on to suggest that there is one activity of human communities which has an uncanny resemblance to the genetically coded activities of social insects, namely the development and evolution of language. Chomsky has postulated that language must be a biological property of the human mind. The capacity to apprehend syntax is genetically coded. Language grows, changes, evolves, independently of any control or planning by individuals or committees or governments. All of us unconsciously and inevitably contribute to its growth and metamorphosis, with as little understanding of how we do it as a termite has of the architecture of its hill. Language, Dr Thomas says, is "the most compulsively collective, genetically programmed, species-specific, and autonomic of all the things we do, and



Greater Horshoe Bat with minute eyes on either side of the nose. The curved portion below the nose and surrounding it represents the nose-leaf, which directs sound waves emitted through the nose during flight. Taken from *Vision in the Animal World* by R. H. Smythe. (Macmillan: London and Basingstoke, 1975.) £6.95.

we are infallible at it." Thus, although an anthropomorphic view of termites is undoubtedly bad science, a termitomorphic view of some of man's activities may be illuminating.

There are many other refreshing comparisons between human and animal behaviour in these essays. For instance, a great deal is known about olfactory sensing among animals and insects; but smells play no part in recognition or signalling between human beings. Because of this deficiency (writes Dr Thomas) "we feel somehow inferior and left out of things." Perhaps this sense has atrophied among humans; but the specific smells are still there, for a tracker dog can follow the trail of a man across the tracks of dozens of other persons. A promising line of research here (writes Dr Thomas) for an Institute of Human Fragrance; for if smells are so specific that dogs can distinguish them, have they any link with the equally specific immunological characters in man?

Readers of *Nature*, accustomed to the severe austerity of prose in which a scientific communication has to be made if it is to be credible, may well ask what relevance these whimsical essays have for them. I think they have considerable relevance, and this is why I think so. In the 1970s pure scientific research is on the defensive. Not only is there the first anti-science movement for over a century; there is also, and more ominous, an air of scepticism about the value of pure science on the part of the Establishment. Research Councils are considering the cost-benefit values of their support for some lines of work. Government-sponsored science has now to be regarded as a sort of trade-relationship between 'customers' (who often do not know how to ask the right questions) and 'contractors' (who are paid to answer the questions even if they are not the right ones). In these circumstances it is essential that the public should understand the value to civilisation of encouraging sheer exuberant curiosity about nature. They will not understand this unless they understand what the scientific attitude to nature is like. The end results of scientific research are well popularised in books, films, and TV programmes; but the public know very little about the conception of scientific ideas, the leap of imagination necessary to ask the seminal questions to which research provides the answers. The future patronage of science by the public may therefore depend on a fresh kind of popularisation. If I had to recommend to a non-scientist a book which gives a vivid impression of how scientific ideas are born, this is the book I would recommend.

Eric Ashby

Problems and progress in theoretical physics

Quantum Gravity: An Oxford Symposium. Edited by C. J. Isham, R. Penrose and D. W. Sciama. Pp. 605. (Clarendon: Oxford; Oxford University: London, July 1975.) £10.50.

The first quarter of this century witnessed two major revolutions in fundamental theoretical physics: quantum theory and relativity. As we enter the last quarter of the century, these two cornerstones of modern physical science are still irreconciled.

Quantum theory was originally developed as a theory of matter, whereas relativity is a description of the structure of space-time and its relationship to gravitation. The latter development of the quantum theory of fields, however, with its spectacular successes in describing electrodynamic phenomena, naturally prompted investigation to determine whether these successes could be repeated for the gravitational field. The only theory of gravity so far tried for quantisation in any seriousness is Einstein's general relativity (and minor modifications thereto), an enterprise which has encountered extraordinarily complicated technical problems, demanding great dedication and courage from would-be quantisers. These difficulties, together with some fundamental problems of principle, have resulted in a whole range of well-tried approaches, all of which have so far failed to yield a satisfactory quantum theory of gravity. Many practitioners, disillusioned with the slow progress of these "frontal assaults", have advocated nothing less than a rejection of the direct use of either general relativity or quantum theory, and propose instead intriguing new principles at a more elementary level of nature. In direct contrast, another popular "second-best" effort has been to try to first cope with the quantum theory of better understood fields which are located in the curved space-time of general relativity, that is, quantum matter in classical gravitational fields.

A whole range of such philosophies and techniques appear in this impressive book. The text, apart from an article by S. Deser, is based on a symposium given at the Rutherford Laboratory in February 1974. There are nine chapters, and although each is by a different author, the organisation and level of presentation are sufficiently consistent to make the book a very useful collection of topics.

The symposium itself was a memorable occasion, because it simultaneously provided a good deal of pessimistic prognosis about achieving a proper quantum gravity using the more traditional techniques, together with the first public announcement of an extraordinary new result about black holes by Stephen Hawking. There is no doubt that this development, which predicts that black holes create particles and "evaporate" away, has provided a great stimulus for research into quantum field theory in curved space.

Hawking's explanatory article is accompanied by one of the most concise and elegant accounts so far of the theory of twistors, presented in two chapters by Roger Penrose and his former student, George Sparling. Penrose's twistor formalism provides by far the most developed and promising possibility of a completely new approach to the structure of space-time and matter.

The more traditional techniques are dealt with by M. J. Duff, with a clear account of covariant quantisation, S. Deser discussing recent Feynman graph calculations and A. Salam, who outlines some results from his long programme of treating gravity from a particle physicist's viewpoint. The main conclusion to emerge from these discussions is the impasse of non-renormalisability; when matter is present, the divergences which always occur in quantum field theory cannot be isolated for the gravitational field in a systematic fashion.

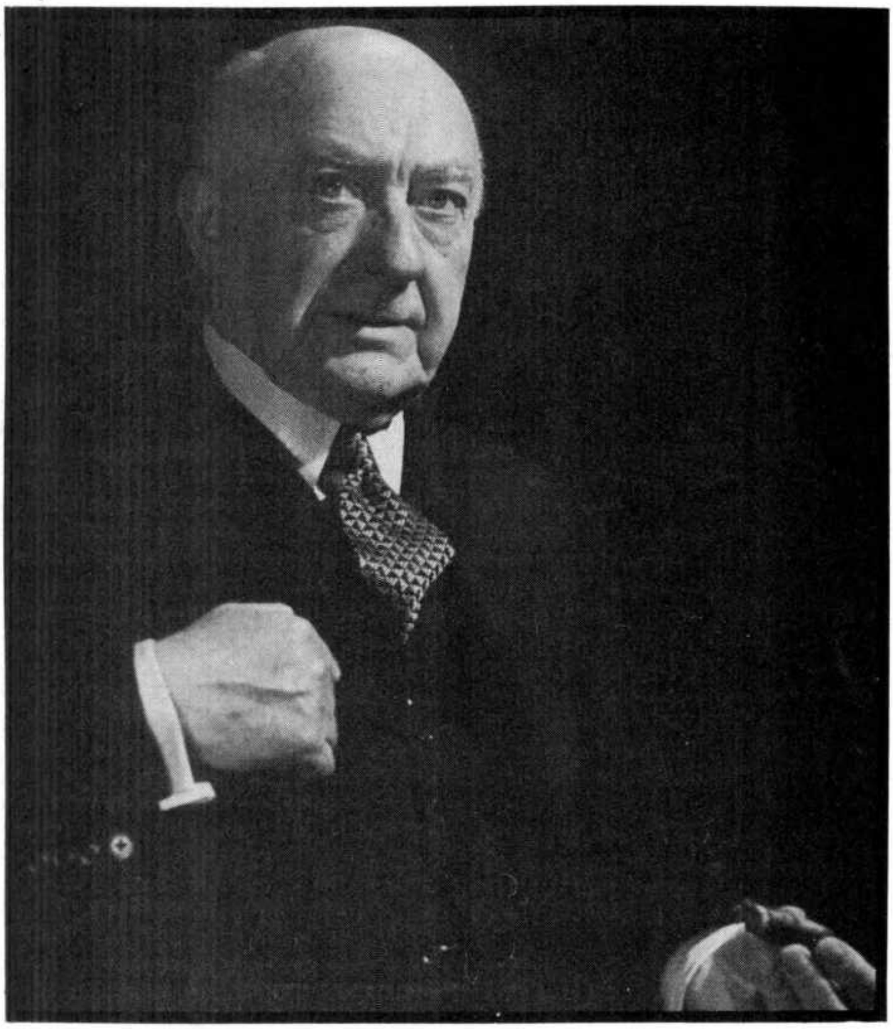
The book also contains a well-written account of some aspects of quantum cosmology—the slightly bizarre technique of quantising the whole universe as a simple mechanical system—by M. A. H. MacCallum. The final chapter carries the unmistakable stamp of J. A. Wheeler in a wide-ranging assessment of the subject, complete with philosophical perspectives and intriguing illustrations. This chapter, entitled "Is Physics Legislated by Cosmogony", is jointly written by Wheeler and his student, C. M. Patton.

No book of this type could be complete without a good review of the whole subject. A useful and very readable account is given at the beginning by an acknowledged quantum gravity expositor and contributor, C. J. Isham.

For the first time the researcher has available in a single volume a broad range of material, edited by three experts, in this most challenging and difficult area of theoretical physics. It is to be recommended to all departments with an interest in cosmology and astrophysics, and more generally to anyone concerned about the really fundamental aspects of physics.

P. C. W. Davies

Portrait of an industry



Baron McGowan of Ardeer. Courtesy Douglas Glass

Imperial Chemical Industries: A History. By W. J. Reader. Vol. 1: *The Forerunners, 1870–1926.* Pp. xvi+563+38 plates. £7.50 net. Vol. 2: *The First Quarter-Century, 1926–1952.* Pp. xvii+569+41 plates. £18.50. (Oxford University Press: London and New York, 1970 and 1975.)

IN the first volume of this work Dr Reader traced the histories of the four major companies—Brunner Mond, Nobel Industries, United Alkali, and British Dyestuffs Corporation—which in 1926 participated in the biggest merger in Britain, up to that time, to form Imperial Chemical Industries. He gave convincing evidence of his ability to digest an immense amount of detailed information and to present it, very fully annotated, in a readable form. Reader's treatise is, however, essentially a business history— with its emphasis on finance, commercial strategy, and trade practices—and the reader with an interest in the history of technology is less adequately catered for, though he will find the cited references helpful. He will learn more about the consequences of technological advances than about their causes and natures. There is, for example, rather little about the basic problems of high-pressure technology—fundamental to ammonia synthesis—and how they were overcome. Nor do we learn much of the technical problems of the switch from coal to oil as a raw material after the war. In a history of a pre-eminently science-based industry, where decisions are determined as much by technological feasibility as by commercial acumen, that is a little disappointing.

In the latest volume Dr Reader expounds his main theme, the evolution of ICI during the first 25 years of its existence. As before, he has had unrestricted access to the company's archives and he has written very frankly of failure as well as success, of the weaknesses as well as the strengths of the individuals concerned. As volume 1 relates, the immediate reason for the formation of ICI was McGowan's clear recognition that the existing units of the British chemical industry were too small to compete effectively with the powerful IG Farbenindustrie formed in November 1925. The merger was very hastily cobbled together—literally as Brunner Mond were on the point of allying themselves formally with IG—and in the early years much effort had necessarily to be expended simply on welding four very disparate entities into a unity which some of them did not really want.

Although a distinguished board was appointed, power from the outset lay with Sir Alfred Mond (later Lord Melchett) and Harry McGowan. After the former's death in 1930 the board elected McGowan chairman and managing director. This unwise dual appointment gave him extraordinary power, of which he availed himself to the full: from 1930 onwards he ruled ICI absolutely. Not until 1937, when he was away in Australia, was his power challenged by the board. Then, just as it seemed that success was within their grasp, what Reader calls "The Barons' Revolt" fizzled out—possibly because of the illness, at the crucial moment, of the second Lord Melchett.

In the early years, ICI's commercial policy was wholly unadventurous. McGowan was a firm believer in limiting production, sharing markets, and—above all—securing to ICI the market in the Empire which its name embodied. To him and his colleagues the Empire was enduring and virtually indestructible: over the years it would provide a reliable and growing market from which all foreign rivals could be excluded, if necessary by making agreements not to enter their territories. It is very reminiscent of Pope Alexander's Bull of 1493 dividing the New World between Spain and Portugal. The idea of competition was positively repugnant. As late as 1941, McGowan wrote that he did not accept "the theory . . . that competition is essential to efficiency". The policy was indeed not unsuccessful at that time but it led to some very serious complications, as, for example, in the case of the Dupont agreement. The United States had very different views of the nature of free enterprise.

It was not the only error. Another was in the great fertiliser complex built at Billingham. Technologically, it was a great achievement, but it proved a commercial disaster when markets could be found for only a fraction of its capacity. Reader brings out one reason for that, other than the slump, very clearly: marketing was defective because ICI failed to recognise the crucial importance of the men concerned and accord them the necessary status. Production methods were good, but it seemed that selling the products —especially to the public as opposed to other manufacturers—was too ungentlemanly to be taken seriously.

The half-hearted approach to profitability was not without national advantage, even if not to the shareholder. There is no doubt whatever, that, over the period here dealt with, ICI was actuated by a high sense of public responsibility. At no time was this better expressed than during the war when the company's resources, not only in production but in very able manpower, was put at the nation's disposal to an extent far beyond the call of duty, with profit as a secondary consideration.

Failures there may have been, but there were resounding successes too, among them polythene and Terylene. Apart from such highlights, however, the substance of the tale told here is one of solid, if unspectacular, achievement over a vast industrial field covering non-ferrous metals, pharmaceuticals, dyes, paints, fertilisers, plastics, fibres, and many other products.

There is one field of ICI's activities deserving greater mention than is given by Reader, and that is the field of publicity and public relations. The company, under the late Sidney Rogerson, pursued an enlightened policy which set new standards. Works were commissioned not only from established artists but also from younger aspirants yet to make their name. Equally high standards were set for the literary style. Older readers will recall such outstanding series of advertisements as 'Ancestors of an Industry', 'Equipment of an Industry', and 'Portraits of an Industry' (from the last of which, incidentally, eight of the illustrations of the book are taken, though the source is not mentioned). Another series, the 'Colours of Chivalry', was ultimately made available as a book which is now a collectors' piece. No mention is made either of *Endeavour*, an international scientific review in several languages, which was started during the war and afterwards established itself as an accepted part of the world's scientific literature. Equally, no reason of modesty should have prevented much fuller mention of the company's enlightened policy towards the universities.

The Postdoctoral Fellowship Scheme, begun in 1944 and only just terminating, gave a start in professional life to well over a thousand able young scientists. Many of them have gone on to outstanding careers in science, and they include two Nobel Laureates.

It is, of course, very easy to criticise a work of this kind on points of detail. Unquestionably, however, this is a masterly account of the formative years of a vast supranational company. Others might have done it rather differently, but it would be difficult indeed to have done it better.

T. I. Williams

Comprehensive biochemistry

Medizinische Biochemie: Lehrbuch für Studierende und Ärzte. 6., Völlig neu bearbeitete Auflage. By S. M. Rapoport. Pp. xxvii+1023+14 tafeln. (Volk und Gesundheit: Berlin, Jena 1975.) DM53.

Comprehensive Biochemistry. Vol. 31: *A History of Biochemistry.* Part 3: *History of the Identification of the Sources of Free Energy in Organisms.* By Marcel Florkin. Pp. xx+475 (plates 64–120). (Elsevier Scientific: Amsterdam, Oxford and New York, 1975.) Dfl.130; $54.25.

Of its kind Rapoport's is one of the best German textbooks of biochemistry for medical students. The book is too detailed for mere preparation for preclinical examinations but is very suitable for keen students, especially those in their clinical years and beyond, who wish to read about the biochemical background of diseases. The material is well selected with special reference to the practice of medicine. The fact that the book has reached its sixth edition since it was first published in 1962 is a measure of its popularity. The new edition is brought up to date with the help of several close collaborators.

What makes the book attractive is its coherence and readability. This is achieved by linking general comments, often of a highly original character, and by avoiding the mere assembly of factual information. The interest of the medical student and medical graduate is maintained by continually relating the biochemical information to normal and pathological organ function. Selected references for advanced reading are given. More frequently than is usual in western treatises are references to Russian investigators and to the importance of their contributions to the progress of the subject.

The text is occasionally interspersed with references to Marxist philosophy—for example, by quoting (on page 35) Engels' formulation of the nature of life: "Life is the manner of existence of protein, the chief property of protein being the continuous exchanges of material with the external environment; the cessation of these exchanges causes the decomposition of proteins". This statement is taken to relate to the dynamic state of proteins, predicted in this passage by Engels many decades before it was experimentally established.

Florkin's work is the first comprehensive effort since Lieben's *Geschichte der Physiologischen Chemie* (1935) covering a field which has grown to vast dimensions in recent decades.

This is the second of four volumes planned as the last section of the 33 volumes of the reference work *Comprehensive Biochemistry*, edited by Marcel Florkin and Elmer Stotz. Florkin, who is writing all the four volumes, is well qualified to undertake this difficult task as he is a biochemist who has researched in many areas, especially in comparative biochemistry and has had the unusual distinction of having been president of the International Union of Biochemistry—an indication of his standing as a biochemist, president of the International Academy for the History of Medicine and vice-president of the International Academy of the History of Science, on account of several major publications on historical aspects of medicine and science.

The present volume is concerned with the history of the sources of energy in living organisms, that is, fermentations, glycolysis, biological oxidations and photosynthesis. The narrative is detailed, giving the key references to the original papers, quoting literally many telling passages, and reporting the story of the complex ways by which the edifice of knowledge gradually took shape—a process which involved not only construction but a fair amount of demolition. Individual scientific publications often give an impression of a continued series of successful experiments because all the disappointing failures (although they may have been essential and unavoidable steps) have been omitted from the final presentation. At a different level this is also true for the history of scientific developments. Florkin illustrates this by relating many of the aberrations which are part and parcel of the steady progress of science.

Students of science are nowadays often disinclined to concern themselves with the historical development of their subjects. They feel that there is so much to read and to learn about the present state of affairs that there is no spare time for concerning themselves with how the knowledge was arrived at, and in particular with reading about aberrations which led to dead ends. Understandable though this attitude may be, for the proper appreciation of scientific knowledge it is essential, especially for those engaged on research, to know how knowledge was arrived at.

The way in which Florkin writes makes it pleasant and easy to get glimpses of the historical background of present knowledge. I feel confident that the book will be enjoyed by many readers, and as a source-book it will remain a standard reference work for a long time to come.

H. A. Krebs

Common sense, wa hae

The Triumph of Truth *by Joshua Reynolds, 1774. The figure on the right portrays James Beattie (1735-1803) holding his* Essay on Truth. *The Angel of Justice is thrusting down the head of Voltaire. The head in the foreground was believed by David Hume to be his: that in the left corner was said to be of Edward Gibbon.*

Scottish Philosophy and British Physics, 1750–1880: A Study in the Foundations of the Victorian Scientific Style. By Richard Olson. Pp. vii+349. (Princeton University: Princeton, New Jersey, and London, August 1975.) £9.20.

"WHERE we try to find models or analogies, they are quite content with laws", so wrote H. G. J. Moseley in his diary for June 1914 after meeting the French physicist Urbain. And if "pictorial thinking" has been a major and distinguishing characteristic of British physics, it is tempting to speculate on how it came about. The interesting thesis of Dr Olson is that it started with the 18th century Philosophical Society of Aberdeen (also known as the Wise Club) whose two most influential members were Thomas Reid, Professor of Philosophy at King's College, and James Beattie, Professor of Moral Philosophy at Marischal College.

The Society was the cradle of Scottish Common Sense Philosophy, so little known today that it has no mention in Bertrand Russell's *History of Western Philosophy*. It arose as a reaction against the atheistic scepticism of David Hume (to whom in fact it owed a good deal) and the materialism of thinkers such as Voltaire and Joseph Priestley. The Aberdeen group, in their efforts to defend moderate Scottish Presbyterianism against the rationalist challenge, had encountered the difficulty that many of us currently face in battling with the prospect of anarchy based on specious rationalism: the latter can lead to conclusions which in Reid's words contradict "certain principles which the constitution of our nature leads us to believe, and which we are under a necessity to take for granted in the common concerns of life". These are moral principles which can be no more proved than the axioms of Euclid and yet which are correspondingly essential as the foundations for a framework of morality.

This seems to be a remote base from which to trace the rise of pictorial thinking in British physics, but it is what Dr Olson sets out to do:

> "The basic aim of this book is to present and to establish the probability of a hypothesis regarding the development of the exact sciences—that is, that many of the important characteristics of the exact sciences in Scotland, and subsequently throughout Britain can be accounted for by the fact that Scottish scientists adopted a particular set of methodological and epistemological attitudes which were clearly articulated by a group of moral philosophers collectively known as the Common Sense School".

Perhaps the most suggestive argument is that with its reliance on common sense plus a few moral axioms, Scottish philosophy had greater faith in the pure "geometry of visibles", proving results by Euclidean arguments, than in analysis, where the algebra of infinite series was known to be dangerous, and where some of the entities such as the square root of minus one had no common-sense physical interpretation. Certainly, there was strong interaction in the Scottish universities between the moral and the natural philosophers (Beattie was in fact appointed to the Chair of Natural Philosophy but exchanged it the same day for that in Moral Philosophy) and undergraduates were exposed to both influences in the traditional Scottish degree.

And there was plenty of good teaching to be had: Reid held with Bacon that the stages of human knowledge were "like steps of a ladder" in which it would be "fruitless to skip directly from bottom to top"—a lesson often ignored today with disastrous results in school teaching. We find John Playfair distinguishing between hypothesis and theory:

> "Hypotheses are explanations which have no evidence independent of their ability to account for the phenomena in question while theories are founded on facts known independently of the phenomena to be accounted for".

And William Hamilton extended Occam's Razor into the Principle of Parsimony:

> "neither *more* nor *more onerous* causes are to be assumed than are necessary to account for the phenomena".

Again, Hamilton spoke of

> "the highest faculty of the mind—that of tracing the analogy of unconnected observations of evolving from the multitude of particular facts a common principle, the detection of which might recall them from confusion to system, from incomprehensibility to science".

Hamilton's colleague at Edinburgh, J. D. Forbes (of the bar and glaciers, and the Chair of Natural Philosophy) wrote

> "The importance of analogies in science has not, perhaps, been sufficiently insisted upon by writers on the methods of philosophizing. A clear perception of connexion has been by far the most fertile source of discovery".

Dr Olson ascribes the demise of the Scottish common-sense tradition to Forbes because his advocacy of greater specialisation in science at the undergraduate stage dethroned moral philosophy from its paramount place in Scottish education. But he as well as Hamilton influenced their pupil, Clerk Maxwell, who all through his life was fascinated by analogy—for example asking the question in a postgraduate essay "Are there real analogies in nature?", and repeatedly stressing the fruitful function of analogy throughout his papers and addresses. As a useful to alert potential readers to culmination, his Electromagnetic Theory showed him to be the greatest of all masters of analogical thinking.

This may be the point at which to mention some very minor blemishes in the book, for Maxwell spent his boyhood not in Aberdeenshire (p. 287) but Kirkcudbrightshire. Melloni's Christian name was Macedonio not Marcello (p. 227) and Poynting's initials were J. H. not M. H. (p. 328), and there are occasional mispellings.

Whether through common-sense Philosophy or not, the Scottish contribution to science up to 1870 was formidable. Besides those of Forbes and Maxwell it is easy to recall many names: Black, Brewster, Brown, Graham, Hutton, Leslie, Lyell, Nicol, Rankine, Ritchie, Robison, Tait, Waterston, Watt, the Gregorys, the Playfairs, and the Thomsons. Quite possibly there was more to it than the common-sense tradition alone: in Britain generally, religious dissent also seems to have been a factor, and the relative decline of the Scottish universities after 1870 was probably far less due to Forbes than to the revival of Oxford and Cambridge, with the abolition in 1871 of religious tests for university entrants. But Dr Olson has produced a book of remarkable interest, well worthy of detailed study by everyone interested in the philosophy of science. **R. V. Jones**

Earth studies

The Earth's Density. By K. E. Bullen. Pp. xiii+420. (Chapman and Hall: London, 1975.) £12.90.

THIS book gives an historical account of developments concerning the variation of density within the Earth. The first five chapters are of an introductory nature covering noted ancient investigations, the determination of the Earth's mean density, spherical harmonics, theory of the Earth's gravitational attraction and the figure and moment of inertia of the Earth. The sixth chapter covers early models of the Earth's density variation including the Legendre–Laplace density law and the Williamson–Adams equation. The meat of the book (chapters 7–17) deals with seismic wave transmission and presents contributions from studies of P and S waves, surface waves, and free oscillations. The penultimate chapter deals with optimum and standard Earth models and the final chapter contains a discussion of the densities of the other planets.

The author, a mathematician, has been foremost in developing Earth models of the classical type based on the interpretation of travel time curves, and chapters 9 and 10 provide a resumé of the Bullen Earth Models of types A and B. Other procedures, such as the Monte Carlo technique and general inversion, are also discussed but somewhat unenthusiastically. The reader will naturally turn to the chapter on optimum and standard Earth models and there he may be disappointed. It seems we still do not have a standard Earth model and the Monte Carlo and general inversion models are treated with scepticism. Bullen's choice of the best model is shown in Fig. 16.1 but it is not clear which model this is and no error bars are shown; it is presumably a combination of Bullen–Haddon models. It is unfortunate that the big conclusion is somewhat obscure as the rest of the book is so beautifully meticulous.

Throughout, the Earth is assumed to be spherically symmetrical, and though lateral variations of density are frequently discussed they are usually dismissed as minor. This is a pity, as with more precise data (using WWSSN and seismic arrays) it is becoming apparent that the Earth is far from spherically symmetrical and that there is considerable local variation in travel time curves. Most of the work described dates from a time before the acceptance of sea floor spreading and 'rapid' plate movements. The outermost layers of the Earth are very mobile and we have few clues as to what causes the mobility, so studies of lateral variations of density are clearly of great importance. We will need to know how big they are and how deep they extend. With that kind of information it may become possible to develop theories to explain plate movements and the earthquakes associated with them. In the meantime, Bullen's book gives us all the hard facts of classical seismology with the warning that they mustn't be forgotten as the lesson for the day. **R. W. Girdler**

The Viscosity of the Earth's Mantle. By Lawrence M. Cathles III. Pp. 386. (Princeton University: Princeton and London, 1975.) £13.10.

THE viscosity of the Earth's mantle is obviously important, not least because of the restrictions that its absolute value and variations with depth place on possible models of mantle convection. Nevertheless, it comes as something of a shock to learn that it can form the subject of a complete, long book. The shock is magnified (or perhaps diminished, depending on one's point of view) by the discovery that, although previous literature is briefly reviewed where appropriate, this is not a textbook but an original work. In short, it is really a long scientific paper which happens to be bound between hard covers. The normal rules of book reviewing therefore hardly apply; proper criticism of this work will only come from other workers in the field over a period of years, rather than weeks or months.

In the meantime, it would seem most Cathles' chief conclusions, especially as one or two of them, if not actually controversial, certainly defy the consensus. The study is based on the assumption that the Earth is a self-gravitating viscoelastic solid; and in the first part of the book the mathematical techniques required to model the isostatic adjustment of such a body are developed at length. The theoretical foundations thus acquired are then combined and compared with geological data on the way the Earth responded to Pleistocene glacial–water load redistributions to deduce mantle viscosity and its variations.

The 'average' Earth model thus constructed has a lithosphere which may be regarded as an elastic shell with effectively infinite viscosity and thickness varying between 70 and 150 km. Immediately below the lithosphere is a low viscosity layer (or 'channel') with an average thickness of about 75 km and a viscosity of about 4×10^{20} poise. The evidence for such a channel is widely distributed geographically, although both the thickness and viscosity of the channel probably vary considerably from place to place. Between depths of 75 and 1,000 km measured from the top of the low viscosity channel, the mantle (defined as the 'upper mantle') has a viscosity of $1.0\pm0.1\times10^{22}$ poise—a conclusion based largely on the uplift of Fennoscandia which has a further 30–50 m to rise.

Most interest, however, is likely to centre on the rest of the mantle (the 'lower mantle') which also has a viscosity of about 10^{22} poise, although at $0.9\pm0.2\times10^{22}$ poise it might be very slightly lower than that of the upper mantle. Many (but not all) workers believe that the lower mantle has a much higher viscosity and that mantle flow is limited to the asthenosphere. But a viscosity of about 10^{22} poise throughout permits full-mantle convection. Moreover, if full-mantle convection is occurring, its main function must be to transport heat from the Earth's interior into space (by way of lithospheric conduction), which can be done effectively only if the upwelling convective limbs are thin. In other words, Cathles' analysis supports mantle plumes, whether cylindrical or sheet-like. Following Morgan, the plumes may then be envisaged as spreading out at the top into the low viscosity channel, with at least a part of the convective return flow occurring uniformly through the mantle as a whole.

Last, but not least, Cathles' model assumes right from the start that viscosity is Newtonian throughout the mantle. This turns out to be entirely consistent with glacial uplift data.

SCIENCE COLLEGE

Pantheism in modern dress

ALISTER HARDY is not the only distinguished biologist to believe in god, or to attempt the reconciliation of that belief with the findings of modern science. In this book* he touches on many of the common arguments, but makes no excessive claims for them, alone or together. Human societies have commonly adopted religions, however disparate—thus, religious belief may be held to be natural to man. Human moral values have varied, and do vary, but to possess them at all is evidence of divine inspiration. The subjective, but clearly not rare, experience of an exaltation, which does not have an obvious explanation in drugs or other definable agents, is in one sense quite real. Hardy sees them all as simultaneously manifestations of natural law (with their analogues present in infra-human species) and of the divine.

Thus he is prepared to see a dog's adoration of its master as equivalent to man's of his gods. Life in a hunting pack gave selective advantages to the capacity to be a follower. The rituals of worship he finds to be ethologically respectable gestures of submission, and this leads him to invite us not to feel embarrassed at reciting the Lord's prayer on our knees. It is nature's way of expressing devotion. But to what? To nature, seems to be the answer.

Indeed, if I understand Hardy's position correctly, it is not easily distinguishable from pantheism, and this will present both his theist sympathisers and his atheist critics with difficulties. The gods which old-fashioned atheists are accustomed to be without are fairly well defined. Their interventions in our affairs are particularly impressive when they flaunt natural law. As swans or as the holy ghost they impregnate women and tangible offspring are the result. They listen to human prayers and may or may not, as they see fit, save the king, connive at the destruction of Troy, or give us our daily bread. But Hardy's version of natural theology must leave us very much in doubt about what it is we are being invited to accept or provoked to reject.

One difficulty lies in his rather ambivalent approach to "paranormal" phenomena. He discusses extrasensory perception (ESP) telekinesis and apparitions, but rather tentatively. Paradoxically these phenomena are only especially relevant if they do not normally occur. If ESP and psychokinesis are reproducible phenomena they are on the agenda of science. If they are not, but occur as rare and unpredictable events which might reflect the decisions of a supernatural power, then it is open to believers to use them in support of the hypothesis of god. We cannot forget, however, that our history is littered with phenomena which started as unpredictable, but are now regarded without undue awe—floods, for example.

We may accept that otherwise sane and sober people have 'seen' apparitions, without admitting that these were objectively visible. Hardy does not imply, for example, that a stranger bursting in on one of Canon Phillips' interviews with the ghost of C. S. Lewis would have seen it too. The question is whether dreams, apparitions, and the like are going to yield entirely to psychological, neurophysiological and psychopharmacological analysis, or are events through which supernatural powers have access to our minds. Hardy seems to want to have it both ways. He accepts scientific analysis and the natural origin of the human faculties he discusses, and he is therefore forced to find the divine permeating nature, but only achieving its full stature with the evolution of man. For this, I suspect, traditional believers will not thank him. A god that is not in some sense independent of nature cannot really compete with Zeus.

Hardy presents his views discursively, modestly, and for my taste in altogether too good-natured a manner. If atheist biologists, such as Monod, are wrong their works should be criticised, not combed for sympathetic quotation. Just a little asperity would have done this book a world of good.

Origins of modern science

ROBERTUS FLUDD ALIAS DE FLUCTIBUS OXONIENSIS MEDICINÆ DOCTOR ET ARMIGER &c

Collection Allen G. Debus

Robert Fludd (1574–1637). From the Integrum Morborum Mysterium: sive Medicinae Catholicae Tomi Primi Tractacus Secondus *(Fitzer, Frankfurt, 1631)*

ALTHOUGH some might be misled by the title of this book† into expecting rather more than is delivered, this is nonetheless a very useful and interesting book. What it does not provide is a serious discussion of the relationships between the three 'themes' of the title. But it does contain useful essays on the separate aspects, as well as a review of the current controversy among historians of the scientific revolution.

The most provocative essay, from the 'mystical' side, is that on Newton's alchemy, by Professor Richard Westfall. Having argued in earlier studies that Newton was not above breaking the rules of scientific method, Westfall describes the enormous bulk and complete technical mastery of the Newtonian alchemical corpus. What else can be said? Newton was clearly committed to chemistry far more than his publications indicate: he was sure that the alchemical tradition contained important secrets; and yet it is highly unlikely that he participated in the mystical aspects of the great work. But was it only chemistry? The matter rests undecided as yet.

A reminder of the importance of the genuinely alchemical and mystical traditions even in the 17th century is given by Alan Dobus. He reviews the career of von Helmont, the mildly Paracelsian chemist, whose sufferings at the hands of the Inquisition are totally neglected in the folk histories of science, perhaps because they were in the cause of a 'prescientific' world view. Also, there is Robert Fludd, the propagandist for a mystical philosophy, who was a close friend of William Harvey, and who defended the circulation of the blood against Gascendi's claims of the existence of the interventricular septum.

Another lively topic canvassed here is the quality of Galileo's reports of his astronomical observations. Paul Feyerabend has accused Galileo of faking these and other reports, and certainly the matter is far from straightforwar.d Although the experts (Righini and Gingerich) disagree, there seems a consensus that it was more a matter of a combination of genuine difficulties, haste and wilfulness than a deliberate or serious deception. Other Galilean topics include an identification by A. C. Crombie of the textbooks from which Galileo derived his early Aristotelean ideas; and a scholars' debate, perhaps unresolvable, on the interpretation of manuscripts purporting to record early experiments on free fall.

A general view of the problem of this book's title is offered by Professor Rupert Hall and Paolo Rossi. Theirs are polemical pieces directed against the advocates of the 'influence' of the alchemical–mystical tradition on the new science. Certainly, they could not find a more knowledgeable and sympathetic antagonist than Rossi, since his studies on Bacon were among the first to exhibit the interplay of continuity and change in the origins of the new natural philosophy from its roots in traditional philosophies, rhetoric, the mechanical arts, and magic. Yet he has chosen to refute rather than assimilate the new claims.

The absence of an ecumenical survey of the problem reflects the fact that at root the debate is ideological. With all that we may now have to admit of the imperfections of the enlightenment and the positivist views of science and its origins, to some it is still a question of rationality in eternal struggle with the irrational. I personally think that Professor Hall is too restrictive, as when he condemns Namierite history as 'irrational' because it ascribes private personal motives for political action. But he and Rossi are together in what seems to be their implicit understanding of the 'irrational', as any view that supposes the faculty of 'rationality' to exist outside the minds of man. By such a criterion much of the hard scientific work on which the scientific revolution was based was accomplished by men who fall wholly or partly under the ban, as Gilbert, Kepler and Harvey. Clearly, the matter needs further analysis.

As a record of a symposium, this is a testimony to the skills of the organisers in bringing together an unusually distinguished and lively gathering. As an exploration of a new facet of a perennial problem, 'the origins of modern science' it represents a good start.

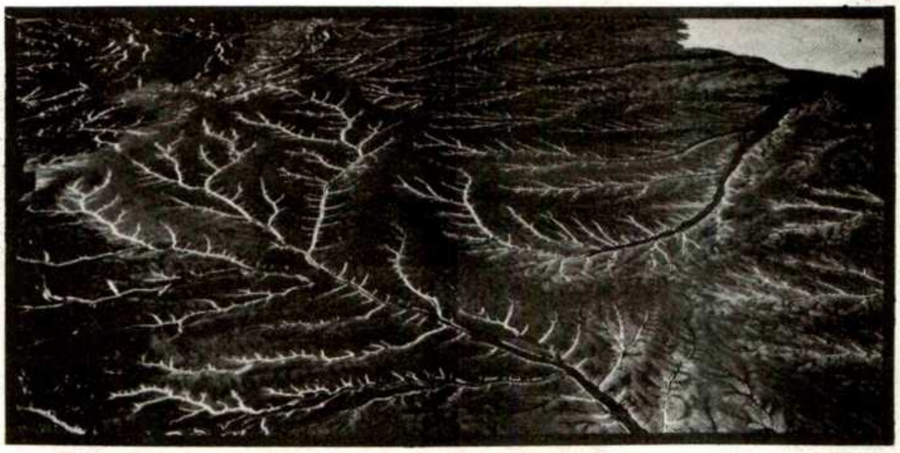
†*Reason, Experiment and Mysticism in the Scientific Revolution*. By M. L. Righini Bonelli and William R. Shea. Pp. 320. (Macmillan: London and Basingstoke; Science History: New York, 1975.) £13.00; $20.00.

Fluvial controversy



Border Island, Arctic Canada

The Work of the River: A Critical study of the central aspects of Geomorphogeny. By C. H. Crickmay. Pp. xvi+271. (Macmillan: London and Basingstoke, January 1975.) £12.00 net.

For over fifty years the author of this book has been concerned with the study of physical geology in the field and the interpretation of scenery in terms of fluvial processes. Here he summarises his findings and theories in a format suitable for students and indeed for anyone interested in river-shaped landscapes.

First, the reader is introduced in an elementary way to the forms of moving water on land surfaces, to the nature of the seasonal work of rivers and to the physical attributes of riverine environments. There follow more advanced discussions on fluvial dynamics and channel equilibrium relationships, with much on grade and interesting comments on other aspects such as cavitation. The erosive work of rivers is then outlined with special attention to base level and a chapter is devoted to examining the hypotheses that constitute the beliefs of several schools of geomorphology.

How then does the author interpret real scenery or landforms seen in the field today? To him the key lies in the great difference between the rate of erosion in river valleys and on flat areas. His main postulations are the hypothesis of unequal activity and the concepts of activeness and stagnancy in landford development. "Some areas of the Earth's surface are almost immune from the postulated [by others] universal destruction by wasting". Ground that is nearly flat or gently sloping (that is, with slopes of under about 5°) makes up the main part of the land surface of the Earth. This abundance of flat land in patches of all sizes up to vast expanses "demonstrates that most denudation is horizontally pursued" by the lateral swinging of rivers mainly at grade. Natural scenery consists of an endlessly varied combination of flats and slopes but since absolute horizontality is rare the Earth's surface may be classified into very gentle gradients or flats and steeper gradients or slopes. Their most significant general relationship is the repetition of one above the other vertically. The flats are stagnant, the slopes active. If stagnant, a geomorphic form may persist almost indefinitely. Although rivers are active erosion agents and wasting may break down all steep slopes, there are certain tracts that survive this destruction because they are out of its reach. When the peripheral flatness extends into the central remnants and predominates there, the land has become a true *Endrumpf*. The ultimate product can only be one broad, low level flat.

These general assumptions mean that most existing scenery was made in time long past and is today essentially relic material. Mountains are areas of "activeness", and the author takes the view that "periods of deep diastrophic calm" are longer than epochs, such as the present, which are characterised by diastrophic agitation and frequent uplifts. The inclusion in the arguments of what to many readers will seem the obvious and the controversial is characteristic of the whole theme. But much of the accepted creed is clearly stated and will be of considerable practical value to earth scientists. Controversy seems inevitable in these natural sciences. For example, is continental drift or mountain building ever still? What is the base level of erosion when low tide mark is far below sea level? Would not high tide and waves consume any flat land mass at base level? But this is the sort of controversy the author deliberately sets out to provoke. Students and earth scientists will find his book a stimulating addition to their bibliographies and as beneficial as a dose of vitamin C after a long season of hibernation.

Robert P. Beckinsale

Evolution of algal ultrastructure

THE green algae are now generally accepted as the evolutionary progenitors of land plants and this book* is an attempt to discuss evolutionary trends within green algae on the basis of cell ultrastructure. After a general introduction, six chapters are devoted to a detailed examination of the ultrastructure, cell division and reproduction of an order of the Chlorophyta. Within each order a restricted number of genera are used to illustrate the diversity of cell structure and reproduction. This approach, although suffering from the potential hazard that the genera selected may not be representative of their order, has been necessary because of the lack of sufficient ultrastructure studies of many green algae. The description of each genus is accompanied by numerous light photomicrographs and electron micrographs (both transmission and scanning), many previously unpublished, which are of consistent good quality and well reproduced. The profusion of photographs accompanying some genera has unfortunately resulted in a loss of synchrony between the text and relevant photomicrographs, such that the reader is obliged to constantly refer to figures several pages distant from the text.

The final chapter is devoted to a discussion of possible evolutionary trends within the green algae by comparison of certain ultrastructural characters. It commences with a list of suppositions concerning primitive and advanced characteristics. The unicellular condition, the possession of basal bodies, flagella, a closed centric spindle, a phycoplast and cell division by furrowing, are deemed to be primitive features, whereas it is suggested that evolutionary advancement can be detected by a colonial tendency, a phragmoplast and cytokinesis by way of cell-plate formation. It is on the basis of the presence or absence of these characters that theoretical evolutionary lines are constructed.

The acceptance of a chlamydomonad cell as the ancestral type of all the green algae is disputed and the hypothesis advanced that this type of cell was the progenitor only of phycoplast-containing green algae. It is argued that the archetypal cell of the other green algae was more like that of *Pedinomonas* (Prasinophyceae). From this ancestral flagellate unicell there developed the filamentous form along two distinct lines. The siphonous line (that is the coenocytic condition) is seen as an evolutionary *cul-de-sac*, whereas evolution by way of ulotrichalean types is suggested as the line leading to the bryophytes and eventually higher land plants.

The arguments for these proposed evolutionary lines are well presented, although occasionally repetitive, and the importance of ultrastructural evidence for evolutionary trends, and also taxonomic classification, is strongly emphasised. The main criticism of this significant work must surely be its price. This has presumably resulted from the inclusion of almost 800 individual photomicrographs, but must place this book well beyond the financial reach not only of students but also of many individual research workers.

Evolutionary sex

THIS is an excellent little book† on a big subject. One would think that a topic of such great interest would by now have been adequately understood. On the contrary, within the past few years the evolutionary reasons for the phenomena of sex have become increasingly anomalous.

A few years ago it was suggested that the very existence of sexual reproduction constituted a paradox. For if an organism reproduces by meiosis and recombination with a partner, it 'throws away' half of its genes. An organism that reproduced asexually would have twice the number of its genes represented in the next generation than a sexual one. For sexuality to be selected, an organism would have to possess twice the fitness of asexual ones, and this seems too high.

Presumably, stimulated by this apparent paradox, Williams has undertaken a series of conceptual studies that show how and why this does not really follow. Some of his models are quite convincing, and we are relieved to learn that there are a number of situations in which the fitness of the sexual creatures is high enough to enable sex to evolve. He does not, however, manage to come up with a very satisfactory explanation of why so many sexual organisms exist that do not fit the model. The explanation he proposes is historical accident. He argues that the present-day organisms that should not be sexual are descended from ones that should, and the change for some reason was irreversible. This may be so, but perhaps more adequate hypotheses are in order.

In addition to the big problem, William discusses a number of other issues in the evolution of sex and of hermaphroditism, masculinity and femininity, and some issues in group selection. A number of these matters are given only cursory treatment. For instance, sexual selection is not covered, although sexual dimorphism is reproduction. These include aspects touched on. And the topic of hermaphroditism is made to seem more simple than it really is. I would have appreciated a somewhat longer discussion of these peripheral issues, with more empirical support. Indeed, the lack of facts has been a major drawback in the literature. Although Williams has considered the facts seriously, the reader will perhaps feel a need for more data.

If the facts do not accord with theory, one corrects the theory. Williams's book substantially increases the opportunities for both theoretical and empirical research. Perhaps evolutionary biology is going through a stage like that in astronomy when the epicycles began to become an embarrassment. The time may be ripe for a bolder approach to the subject, and for "theories more pleasing to the mind."

Pollution of the atmosphere

The Changing Global Environment. Edited by S. Fred Singer. Pp. viii+423. (Reidel: Dordrecht-Holland and Boston, Massachusetts, 1975.)
Cloth Dfl. 95; paper Dfl. 50.
Chemistry of the Atmosphere. By Murray J. McEwan and Leon S. Phillips. Pp. ix+301. (Edward Arnold: London, 1975.) £9.75.

ANYONE curious about the atmosphere and pollution on a global scale will probably enjoy reading these two books. *The Changing Global Environment* is a collection of scientific papers. It gathers together information and ideas of the decade 1963–73 on the possibilities of man-induced adverse changes in the global environment. In the introduction William Kellogg presents a convincing and balanced overview of the possibilities of man-induced climatic change. The authoritative but disparate views of climatology of Murray Mitchell, Reid Bryson and Syukuro Manabe have been expressed elsewhere but they are well worth having side by side in one volume. This is true also of the other sections which concern such problems as ocean pollution and the disturbance of the nitrogen cycle of our planet. Robinson and Robins efficiently summarise and bring up to date their inventory of the sources of atmospheric pollutants and compare them with the outputs of the same compounds from natural sources. The book comforts neither the doomster nor the advocate of unrestrained industrial growth but most of the papers are thoughtful and thought provoking, and will make this collection valuable for a while as a source book for those concerned with global pollution problems.

Just as the environment is changing rapidly so is our knowledge about it and inevitably such a collection has the frozen quality of a group photograph. The participants of the debate all seem to have been caught in mid-sentence. The slightly unreal air of this book is well captured in the second paragraph of the introduction: 'We are now in a period of extensive glaciation. The previous interval occurred 300–250 Myr ago when even the Sahara was glaciated. Of course at that time it was in the position of the South Pole'.

Almost all the authors are American and they occasionally forget that the US is not the world, but this is an inevitable consequence of the real concern in America over global environmental problems and of their generous support of research in the field. By comparison we in Europe tend to take a regional view and a similar collection of European papers would be dominated by the impression that pollution and sulphur dioxide were synonymous. Elsewhere in the world with but few exceptions a narrow parochialism prevails on this topic.

The second book *Chemistry of the Atmosphere* is a lively and enthusiastic textbook of chemical aeronomy. Again the theme is set in the second paragraph of the introduction. 'To a chemist the atmosphere appears as a continuous large scale photochemical experiment. As an experimental system it is unusual in being agreeably free from wall effects . . .' The book is proudly and unashamedly specialist, so much so that the authors are prepared to recognise this limitation to their approach. They say that even the contributions of biologists and poets can be illuminating, but the reader will seek in vain for any information on that part of the air in which the birds fly or where the weather is. Indeed the only mention of the troposphere is in chapter 7 where the chemistry of air polution is considered. This is no criticism of a book which is a splendid introduction for students of chemical aeronomy and for those interested in the scientific basis of important contemporary global problems such as the alleged depletion of the ozone layer by odd nitrogen and odd chlorine.

In this fast-moving field no book can be up to date at the time of its publication. Nevertheless the care taken by the authors to emphasise what was unknown at the time of their writing makes the additions and completions of contemporary knowledge fit comfortably with their text. The authors seem to have that personal familiarity with the practice as well as the theory of their subject which makes its explanation comprehensible and a pleasure to read.

Neither of the books enlightens the current issue of ozone depletion by chlorine-containing compounds such as the fluorochlorocarbon aerosol propellants, neither do they consider the probable future issue of ozone depletion by man-induced increases of natural nitrous oxide emissions from the soil. They should be read while their contents are still relevant.

Penguins

The Biology of Penguins. (Biology and Environment.) Edited by Bernard Stonehouse. Pp. ix+555. (Macmillan: London and Basingstoke, March 1975.) £18.50.

THIS book is the first in a new Macmillan series—Biology and Environment. It is a contributive work, thoughtfully edited by Dr Bernard Stonehouse, one of the world's leading penguin biologists. Dr Stonehouse has assembled twenty papers, a mixture of reviews and the results of new research, which he has grouped into six sections and which together form a very comprehensive reference work on penguin biology. Extensive bibliographies at the end of each chapter enhance the book's academic value.

Dr Stonehouse's introduction includes a concise account of the distribution and major points of biological interest for each of the 18 penguin species. At first, this seems a little unnecessary in a book so obviously specialised, but for the non-penguin functional anatomists, physiologists, ethologists, ecologists (and others) who will also find the work of interest, this check list provides both useful background information and a ready appreciation of the size and diversity of the family. Professor G. G. Simpson begins the section on evolution and taxonomy with an updated review of fossil penguins, the first to be published since his earlier catalogue in 1946. A more recent approach to the elucidation of penguin phylogeny is reviewed in a chapter on the results of protein electrophoresis.

The section on anatomy and physiology contains five papers, ranging from a detailed study of skull anatomy, particularly in relation to feeding, to a valuable review of diving behaviour and physiology. A report on thermoregulation in the little-studied Galapagos penguin is particularly interesting. The lion's share of the book goes to the section containing three chapters on temperate and subpolar penguins amongst which the crested penguins, which have received little attention in the past, are the subject of Dr J. Warham's long contribution, the first published comprehensive account of the genus. Six chapers make up the section on breeding and population studies of Antarctic penguins and although, not surprisingly, the much-studied Adélie penguin is well represented, it is refreshing to find that information on other species has been included. Notable amongst these is an account, prepared by members of the British Antartic Survey, of the little-known Chinstrap penguin. A useful review of penguin predators, both at sea and on land, joins a specialised study of Emperor penguins to form a short section on predation and mortality. Adélie penguins figure again in a final section on communication and display, consisting of two chapters which provide interesting examples of different approaches to the problem of describing and interpreting behaviour.

Most of the criticisms which can be levelled at the book are explicitly felt by the editor himself. He fairly points out the absence of papers on long term population studies, parasitology and conservation, and particularly of studies at sea where, for penguins as for most seabirds, relatively little is known. Too often, contributive works of this kind are merely collections of loosely connected, highly esoteric papers but this is not the case here. Dr Stonehouse has skilfully compiled a volume which, in spite of its omissions, is sufficiently comprehensive to wear its title honestly. The book is sure to find a ready place in many libraries.

Endangered species

Breeding Endangered Species in Captivity. Edited by R. D. Martin. Pp. xxv+420. (Academic: London and New York, May 1975.) £12.80; $33.75.

THIS collection of papers marks the beginning of a very much greater realisation by responsible zoos of the role that they should be playing in preventing the total loss of some fascinating and important animal species which are at risk for reasons usually related to man's rapid expansion.

The editor is to be congratulated on bringing together in a readable form, papers which vary in the quality of presentation and of content. Nearly all shed light on the task of maintaining viable breeding groups in captive conditions, especially those that are rare in the wild. A number of authors have drawn attention to the broader issues involved in the development of breeding programmes, and some rightly demand a more pragmatic approach by those controlling animal collections to ensure the maintenance of viable breeding groups on an inter-zoo co-operation basis, thus avoiding the dangers of inbreeding and gene-pool loss. Attention is also drawn to the need to maintain rare animals in a number of collections rather than concentrating them in one area where they may so easily be destroyed by disease or other misfortune. Views are expressed as to whether the genetic changes occuring during, and possibly as a result of, captive breeding will fit animals for a return to a natural environment, especially if re-introduction is attempted after a number of generations in captivity.

Pilot projects to ascertain the problems of re-introduction are suggested, and these could as easily involve common species. In this context, it should be remembered that today's common breed could so easily be tomorrow's rarity, and that every item of information that might help to maintain these in a productive captive state should be available to those involved in this.

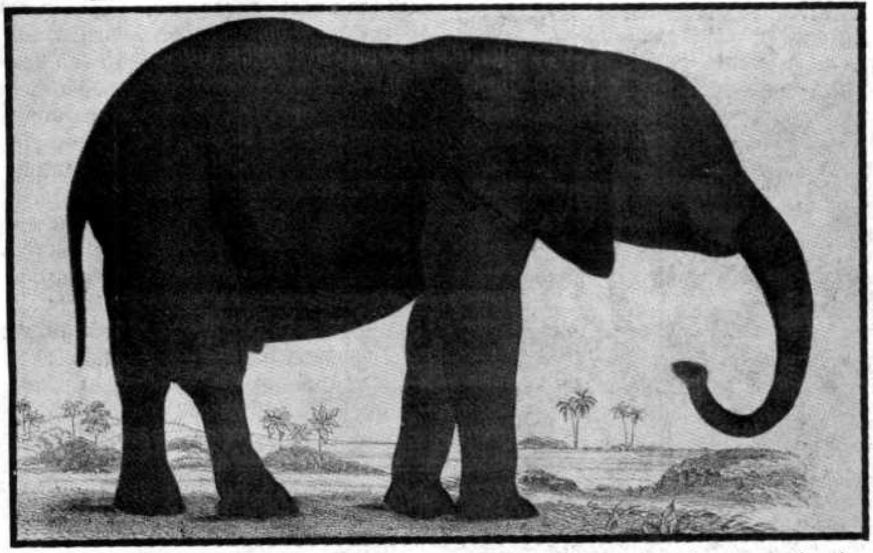
The Fauna Preservation Society, one of the conference sponsors, has been for many years responsible for the conservation of animals in their natural state, and has been perhaps identified with conservationists, many of whom are still unable to see the value of breeding endangered species in Zoological Gardens. The other sponsor, the Jersey Wildlife Preservation Trust, on the other hand has been at the forefront of those zoos who specialised in breeding endangered species; but in this field also there are regrettably still many zoos who do not believe their function is other than to entertain. It is the directors of these zoos that Gerald Durrell would like to see on the endangered species list.

The publication is unfortunately rather highly priced; unfortunate because it should be an essential part of every zoo director's library, and not just those Directors who are already aware of what has to be done. In a wider sense it should be on the bookshelves of all those who are deeply concerned with the future of existing wildlife and wild places.

This collection of papers may be the first of a succession of books on the important challenge of ensuring for moral and other reasons, species of animal life for the aesthetic and other pleasures of future generations. Most first efforts have their imperfections, and this is no exception, but it does form a foundation on which to expand.

R. J. Wheater

Elephants of Uganda



Mary Evans Picture Library

Elephants and their Habitats: the Ecology of elephants in North Bunyoro, Uganda. By R. M. Laws, I. S. C. Parker and R. C. B. Johnstone. Pp. xii+376. (Clarendon: Oxford; Oxford University: London, July 1975.) £15.

THIS is ecology on a grand scale. The stage is the 1,200 square miles enclosed on the west by Lake Albert and on the north and east by the great sweep of the Victoria Nile from Lake Kyoga to Pakwach. Elephant biology dominates the action, but the book encompasses the whole environment, one in which the changing scene is governed by the population dynamics of the elephant and man's relationship with these animals—in competition or conservation.

Before World War II, and for some years after it, information about elephant populations was plentiful but usually wrong. The most experienced game wardens and hunters had totally inadequate ideas about elephant numbers and movements, especially in the tall grass and forest areas such as Bunyoro. Advance has come with the development of the National Parks, and with the expansion of air travel and the use of aerial surveys. Richard Laws, a Cambridge zoologist, was foremost among the pioneers who applied modern ecological methods to populations of large mammals. He came to Africa after working on whales and seals and has since returned to his Antarctic studies, so that one may suppose him to be attracted by the big beasts and the romance that attaches to them. His approach, however, is matter-of-fact and his research is distinguished for its intellectual rigour allied to a grasp of administrative and economic problems. In this book he is assisted by a wildlife manager who was born in East Africa and a forester who has been particularly interested in the Bunyoro district. The result will serve not only as a mine of information but also as a model of what a study of this sort can embrace.

This book is not about all "Elephants and their Habitats". The subtitle perhaps more strictly describes the content, but it is undeniably relevant to all elephant management. I think it is safe to say that there is no other mammal population in which growth, nutrition, habits, reproduction, age structure and behaviour has been so thoroughly studied in relation to climate, flora and fauna and land-use of its habitat. In north Bunyoro, "by mutual agreement between the individuals, departments and companies involved, all the relevant information has been pooled to form the basis of this book".

There are no adventure stories of life on safari here, and this is not a 'coffee table' volume. It is true practical science, an authoritative account, detailed and for practical purposes complete, for the use of students and the guidance of administrators. After reviewing the history of the region and man's use of it, the authors describe its flora and fauna in some detail before embarking on six chapters of elephant biology. There follows a chapter on the changes in habitat associated with past management and a cropping programme involving both elephant and hippo. In the final chapter the authors put forward recommendations based on their analysis of the ecological factors involved—recognising aesthetic and cultural considerations, but regarding economic considerations as "of overriding importance". Many will judge this book indispensable. **John S. Perry**

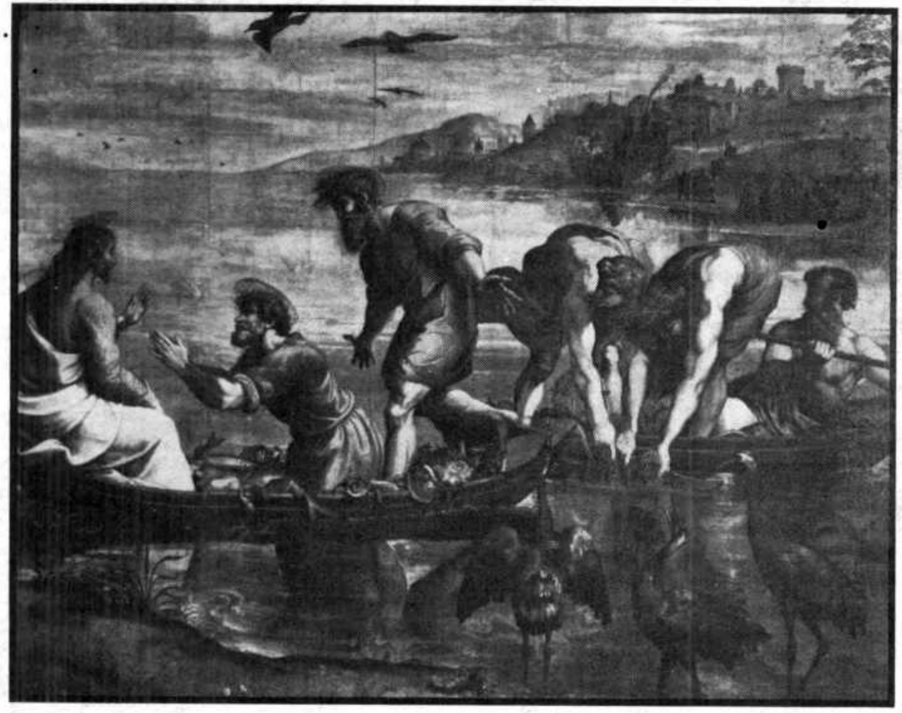
Prospects of the sea



Miraculous Draught of Fishes by Raphael. Courtesy V. & A. Museum

IT can be very salutary to be reminded that nearly 50 years have passed since one became a student, in 1928, the year in which the first edition of "Russell and Yonge" appeared. Well before that I had been introduced to Frederick Warne's well-known (and well-read) *Wayside* and *Woodland* books, but in several respects the appearance of *The Seas* must have marked a high point in the series. This compact book provided, as nothing else had done, for both layman and student, a concise view within one cover of what was then known of the seas and the life they maintain, with a glimpse of the ways in which they were being investigated. For the beginner, and later, the book was as fascinating as it was useful and, as in the whole series, the lavish illustration was a particularly valuable feature. Although it would not be correct to suggest that for this student it was instrumental in deciding on a career (there were other influences) it had its place—and the privilege of being able to listen to the authors at the Bristol British Association meeting in 1930, following their return from the Great Barrier Reef Expedition, also played its part. These two authors must undoubtedly have influenced many in their choice of a career, and aided far more in acquiring a sense of perspective about the life, largely hidden, that inhabits the greater part of the earth's surface.

Very rightly, the book sold well, with a second edition in 1936 (two reprints) and a third in 1963. Now a fourth and extensively revised edition has been produced in a larger format. As the blurb reasonably implies, not many co-authors are fortunate enough (in several ways) to deserve, and secure, such treatment. Not many co-authors, of course, have themselves contributed so much by way of original work (in remarkably complementary ways) to the progress made in marine research over 50 years. Both are still contributing and it is no mere coincidence that each should have been knighted for his service to science.

Their new book is still presented within the old, and very adequate, plan but it is brought up to date in many places. Indeed, collation of the latest edition wtih the old is a fascinating task, and it is a tribute to the care given to the earlier editions that so much can stand today, mainly with supplements rather than major alterations. There are, however, two new chapters—one on "Sensory Perception" and another on the "Influence of Man on Marine Life"—and the earlier chapters on "Shellfish" and "Products from the Sea" have been brought together under the title "Marine Exploitation and Cultivation". So much has taken place, and been discovered in marine research since 1927 that, in a still compact introduction only some of the highlights can be revealed, and interesting discussions might be developed on just what is (and will be) held to be the most significant. For example, there might have been a case for saying a little about the new knowledge gained concerning continental drift, and inferences it may have for life in the seas. Again, although the Torrey Canyon and Santa Barbara episodes are mentioned, there is no reference to taking oil from under the sea in the new chapter on the "Influence of Man", although this is already influencing marine life, and will do so more and more, as also many of the men who earn their living by exploiting the seas in other ways. But where should one stop in what is necessarily an introduction to a vast subject?

This edition also has a largely new set of illustrations, for many of which the authors are indebted to Peter Stebbing, although several of the "classic" plates have been retained, together with a number of photographs by D. P. Wilson. The earlier frontispiece, however, showing a moderately equable sea has been replaced by a striking dust-cover enetitled *Rough Sea!*

This edition should prove as valuable and stimulating as ever. It is well produced and readable in both senses of the work. Even at £6.95 *The Seas* is still, in these days, a good buy.

THIS book† is the latest addition to numerous volumes on the nature, life and problems of the sea which have appeared over the past few years. Dr Bellamy, however, has his own approach to the subject. Starting with a general description of the oceans with a very adequate account of the principal factors influencing sea and shore as environments for life, he proceeds with descriptions of the various forms of marine life and so to some account of the oceans as a source of food and other resources with the effect of man on this, largely by way of pollution.

This book is intended for the general reader who will get a very adequate general idea about the oceans from the initial chapters which include some account of the probable origin of life with an account of cell and plant life in the sea, leaving a description of animal life to occupy the following 16 chapters, almost two thirds of the book.

Here Dr Bellamy essays to describe the full range of marine invertebrates to a general reader and it is clearly on his probable degree of success in this venture that any estimate of this book must largely be based. Although aided by numerous black and white and coloured illustrations, one still wonders to what extent he will accomplish his purpose.

---

*_The Seas: An Introduction to the study of life in the Sea._ Sir Frederick S. Russell and Sir Maurice Yonge. Pp. x+283+48 plates. Fourth edition, completely revised and extended. (Warne: London and New York, September 1975.) £6.95 net.

†*The Life-Giving Sea.* By David Bellamy. Pp. 320. (Hamish Hamilton: London, September 1975.) £5.75.

The sponges, to which he possibly devotes too much attention, emerge as much less organised than they really are. The coelenterates get more judicious treatment although there is confusion between the stinging coral, *Millepora,* and the very different blue coral, *Heliopora* and the plate opposite page 65 showing an unnamed green coral is mystifying. The only chlorophyll in corals is contained in the brown zooxanthellae. The mushroom coral, *Fungia,* cannot "move about on the bottom"; it can only (if small enough) be carried about by water currents, although it can right itself if turned over and uncover itself when buried under sand.

The author is clearly fascinated by ctenophores (comb jellies), describing not only British species but the glorious Mediterranean Venus' Girdle and even the exotic *Coeloplana* and *Tjalfiella.* But this is unfortunately balanced by a very inadequate treatment of the far commoner and vastly more important Crustacea and Mollusca, his accounts of which one feels would only give a confused idea to any previously uninstructed reader. There is no mention of the ubiquitous amphipods and isopods; moreover crabs, lobsters and shrimps do not have nauplius larvae.

The structure of a bivalve mollusc is only indicated by an inadequate diagram and indeed throughout there is little mention of benthic organisms generally (apart from fixed algae) in spite of their fundamental importance in marine productivity. Echinoderms are better treated although the arms of brittle stars are surely not "festooned with tube feet".

There is much better treatment of the fish where, of course, even an unexperienced reader can meet the author part way. The major forms and modes of life are well described in the text and illustrated in the figures. Dr Bellamy continues through marine reptiles and birds to sea cows (a pity he says so little about these, with only an uninformative photograph of a manatee) to the whales, and a very interesting account of the work of Gerald Kooyman on the Weddell seal. As to the Californian (rather than the "southern") sea otter, the story is now changing, with the protected animal devouring every available invertebrate, including worms!

The final chapters cover marine productivity, including coral reefs, with the extent to which this is being affected by man (although whether man's activities are responsible for the current plagues of coral-destroying crown-of-thorns starfish is dubious). But here Dr Bellamy most fittingly emphasises the significance not merely of the evolution of diverse animal forms but of "an integrated living system that mirrors the potential of the environment". One also approves his description of "pollutants" as "enrichers, suspenders, cloggers and killers" and his discussion on the relative importance of these categories.

Criticism could be made of various statements including the strange confusion—at any rate to one of this reviewer's age—of Rider Haggard instead of Conan Doyle as the originator of the *Lost World.* The plumose anemone is repeatedly termed "plumrose" and has *Gonyaulax* now become *"Gonyaulux"*? A final criticism concerns the author's tendency to write down to a popular level, to refer to leeches (beautifully adapted animals) as "nasty, horrible, revolting", to edible Crustacea as "mouth watering", and the use of "mind boggling" elsewhere.

Nevertheless this book has the major virtue of enthusiasm, reflecting so much of what David Bellamy has personally seen and done. He makes admirable use here and there of statistics, and the illustrations, although inevitably varying in quality (the one claiming to represent a fiddler crab surely doing so in error), are generally both apposite and informative. And finally, this is a most pleasant book to read.

C. M. Yonge

Dynamics of fishing

Marine Ecology and Fisheries. By D. H. Cushing. Pp. xiv+278. (Cambridge University: Cambridge, London, New York and Melbourne, July 1975). £9.00; $27.50, hard cover: £3.90 paperback.

FEW attempts have been made in the past to bring together the population dynamics approach to fisheries science with the more fundamental aspects of marine ecology. Fisheries scientists concerned with heavily exploited stocks have, naturally, been preoccupied with stock assessments, fishing mortality and recruitment and have thus been concerned largely with adult and juvenile fish.

Varying recruitment to individual year classes of fish has long been recognised as a factor of major importance. The events which lead to variations in recruitment, however, are of such complexity that they have understandably discouraged efforts to integrate them into models of fish populations. They, in fact, embrace virtually the whole of marine ecology. Nevertheless, if we are to reach any real understanding leading to an ability to predict, they cannot be ignored.

Dr Cushing's book embraces material he used in a series of lectures at Oregon State University and I, personally, am sorry I did not hear the lectures. His competence in presenting the subject in written form makes it readily assimilable, and the presentation is a pleasing example of the competence of Cambridge University Press.

The first four chapters are devoted to a useful condensation and appraisal of information, widely scattered in the literature, concerning the process of organic production in the sea. Space and time variations in the broad ocean areas are dealt with first, then the production cycles in the highly productive but unstable upwelling and divergence regions. The role of nutrients is then considered and, finally, the various attempts which have been made to model organic production in the sea are reviewed.

The next three chapters assemble information about fish stocks and migrations, their growth and mortality, and population dynamics. Again, this is a valuable condensation of a great deal of material widely scattered in literature from all over the globe.

The author then embarks on an exercise integrating our knowledge about the stocks of herrings off northern Europe with the organic production cycles—establishing a convincing correlation. Herring are planktonic feeders but behind the simplicity of this statement, the true complexity of the foodweb which culminates in herring is perplexing. It is illustrated in a critical feeding path diagram and the author explores the approaches which can be adopted to express the relationships in terms which can be handled in models.

Temporal changes and the influence of climatic factors are considered in the two following chapters and the book concludes with a discussion of the interaction between fisheries research and marine ecology, carrying a clear message that they can be mutually beneficial.

Students will find the book extremely useful and marine ecologists and fisheries biologists will broaden their outlook by consulting it.

R. I. Currie

Fruition of flowering plants

Bulbous Crowfoot, Mary Evans Picture Library

The Morphology of Angiosperms: The Structure and Evolution of Flowering Plants. By K. R. Sporne. Pp. 207. (Hutchinson: London, February 1975.) £3.50 cased; £2.00 paper.

THE study and interpretation of plant morphology is a subject which captured the imagination, and occupied much of the research effort, of botanists of the nineteenth century. Yet within the last few generations the emphasis of teaching and research has swung away from the structural and toward the physiological, biochemical and ecological aspects of the subject. Although such emphases are bound to change as new techniques and ideas come to prominence, it is sad that so many of those who teach in our schools and universities have come to regard all matters structural as the descriptive studies of a former era and therefore irrelevant to their needs. Even the word 'descriptive' is held in disrepute in some quarters. Undoubtedly the lack of a good modern synthesis of morphological concepts has contributed to this situation and for this reason Sporne's trilogy of morphological texts is especially to be welcomed.

This final book, dealing with the angiosperms (previous ones have covered pteidophytes and gymnosperms), couples a careful selection of information with a lively and readable style—both necessary attributes of a book which seeks both to enlighten and to interest the student. The arrangement of its contents is traditional, dealing with embryology, then the major structural features of the angiosperms, meristems, root, shoot, pollen, ovules, seeds, and so on. Yet the material of this book is conveyed in a far from traditional manner. There is a strong underlying theme of evolutionary trends, which both provides a unity to the examples quoted and also serves to raise those basic questions of origins which should be central in the minds of all biologists. Sporne's book excells in that he is prepared to raise these questions and attempts to answer them even at the risk of overgeneralisation.

The paucity of fossil records relevant to angiosperm phylogeny means that comparative morphology is still the most useful approach to the questions of evolution within the group. Sporne describes the modern numerical work in this field and, although he recognises its weaknesses, can unashamedly state that "a policy of caution would take half of the fun out of research". Perhaps it is the overcautious approach of his predecessors which has taken much of the fun out of plant morphology, but this lively, informative and entertaining book should succeed in injecting some renewed vigour into this neglected subject. It will be weclomed, and should be read by all students and teachers in the field of plant biology.

P. D. Moore

Science as an obstacle course

Problems of Scientific Revolution: Progress and Obstacles to Progress in the Sciences. (The Herbert Spencer Lectures 1973.) Edited by Rom Harré. Pp. vi+104. (Clarendon: Oxford; Oxford University: London, July 1975.) Paper £1.75 net; Boards £4.00 net.

I MUST be honest. I have never actually managed to get around to reading much philosophy of science, except for Medawar in passing. My reactions to this book are therefore probably akin to those students who listened to the 1973 Herbert Spencer lectures recorded therein. I hope it is not through naivety that I found most of the lectures coherent and stimulating.

The book has six contributors ranging from practising scientists to professional philosophers. The mixture works well, allowing a wide-angle approach to the subject. As I cannot believe that it is a *sine qua non* of thinking scientists that they subscribe to the views of Sir Karl Popper, however, it is perhaps surprising that four of the six writers are self-confessed Popperians, another one is guru Popper himself, and only B. F. Skinner does not pay explicit homage.

The progress of science is viewed at its most practical level by W. F. Bodmer. He exemplifies the external factors, especially ethical and eugenic, that modulate the progress of genetics and concludes with rather hackneyed advice to scientists on how to assume a socially responsible position. Sir Hermann Bondi is more concerned with the internal forces that operate. He reveals, again by example, the kind of fits and starts involved in any scientific advance and correctly emphasises the reliance of progress on new technology.

The development of evolutionary theory is Jacques Monod's theme. He shows how the coming of molecular biology has not only added unpredictable layers of flesh to the bones of Huxley's synthetic theory but has at the same time converted it into a theory fully liable to Popperian falsification. He also attacks his critics who cannot come to terms with the advent of man by chance, and not by necessity. B. F. Skinner is even more critical of those who cannot overcome the obstacles he sees to the progress of behavioural science. Their fault, he argues with clarity, is in being trapped by an introspective, reductionist approach. Unfortunately he fails to develop his own alternative approach and its controversial application to, for example, behavioural modification.

The least tangible of the contributions is that in which J. R. Ravetz suggests that the way to salvation for the present condition of science lies in the spirit of Francis Bacon. The longest essay, replete with footnotes, is Popper's. It is divided into two parts. The first is concerned with his fallibilist theory but with several unexpected diversions. The second part deals with hindrances to scientific progress—economic factors ("big science may destroy great science"), intolerance plus dogmatism and, most pernicious, the danger of allowing scientific revolutions to become blurred by ideological entrenchment or the fashion-mongering of intellectuals.

This book is ideal for undergraduates or postgraduates. By and large it avoids being doctrinaire and is sufficiently down to earth to have a lasting and beneficial influence on its readers.

Peter Newmark

Science Between Culture and Counter-Culture. By C. I. Dessaur, Aren Naess, Everett Reimer, Hans J. Eysenck and A. G. M. van Melsen. Pp. 108. (Dekker and van de Vegt: Nijmegen, 1975.) Dfl. 19.50.

THE debate that has developed in

recent years between the proponents of culture and counter-culture has often tended to focus on science as the chief target for criticism from all sides. This issue was at the centre of the public exchange of views organised in 1974 for the tenth Lustrum of the Catholic University of Nijmegen, in the Netherlands. Five of the papers presented on this occasion have now been published: a general introduction by Professor Desaur (Nijmegen); an indictment of science on 13 different counts by Dr Arne Naess (Oslo); an autopsy of the education system—"the school is dead"—in the context of world wide transformation of culture by Dr Everett Reimer (Puerto-Rico); a defence of science against indiscriminate rejection which often chooses to ignore uncomfortable facts rather than learn to live with them, by Professor Eysenck (London); a reflection on the place of the Catholic university between culture and counter-culture by Professor Van Melsen (Nijmegen).

Critics of an enterprise such as science which exerts enormous influence on all aspects of society can always find something on to which they can latch. Defenders, on the other hand, can be quick to point out the undeniable benefits arising from scientific research; as a last resort, they can even denounce technology as a monster bred by the power structure—but for which scientists themselves will not claim responsibility, their concern being the quest for knowledge, and the quest for knowledge only.

When conducted on this level—which is more or less that of the papers presented here—the debate on the pros and cons of science is never-ending and inconclusive. It is true that each society has the science it deserves, and not surprising that "science has become the whipping-boy" (Eysenck) of those who are most critical of a society which has founded wealth and might on the exploitation of knowledge. Certainly, not all scientists have been indiscriminate and uncritical servants of that State, but most have.

The debate between culture and counter-culture seems at times merely to reformulate some of the fundamental issues discussed by C. P. Snow many years ago: why do we have two cultures—stemming from the natural sciences on the one hand and from the humanities and social sciences on the other—apparently incapable of nourishing each other? Why is it that the scientific establishment sometimes presents the appearance of a new theocracy? Why has the scientific enterprise tended to become an element of consolidation of the *status quo*, rather than an instrument of change? • These questions remain unanswered.

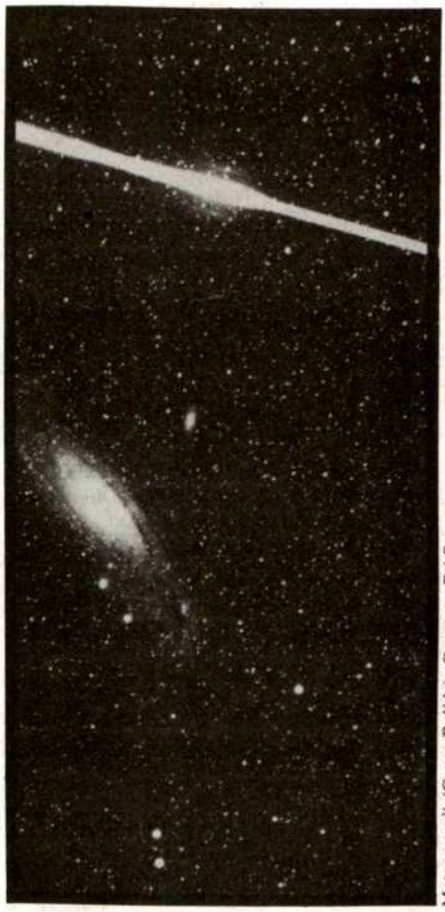
Source of meteorite material



Meteor trail (Great Bolide), Courtesy RAS

Carbonaceous Meteorites. (Developments in Solar System and Space Science, vol. 1.) By Bartholomew Nagy. Pp. xiv+747. (Elsevier Scientific: Amsterdam, Oxford and New York, 1975.) Dfl. 210; $30.95.

RETURNED lunar material apart, carbonaceous meterorites have received more intensive study per available unit mass than any other natural assemblage of minerals. The unique characteristics of carbonaceous meteorites marked them out from all other types of meteorite as soon as detailed studies began in the 19th century. The French chemist, Berzelius, examined the Alais fall—the first carbonaceous meteorite to be recognised—and reported: "These stones are different from all other meteorites because they look like solidified clay and because when they are placed in water they disintegrate and give off a clay-like odour."

Dr Nagy includes Berzelius' report, along with several other early accounts of carbonaceous meteorites (one unfortunately dated 1984), in his lengthy and detailed survey of these objects. The report continues: "The question arose in my mind, does this carbonaceous earth contain humus or a trace of other organic substances? Could this give a hint to the presence of organic formations on other planets?" We have here, at the beginning of work on carbonaceous meteorites, a statement of one of the major reasons for the concentration of attention on them during recent years. They pose the question of whether any of the carbon compounds they contain can be considered biogenic in origin.

The debate over the answer has revolved round two distinct points: the origin of their complex organic molecules and the nature of the so-called 'organised elements'. Dr Nagy, who has been deeply involved in the investigation of both aspects, devotes over half of his book to this debate. He explains clearly the problems entailed in deciding about origin from physicochemical analysis alone. As he remarks in passing: "Were it not for the fossil remnants in coal, one would most likely still argue its origin." Above all, there is the problem of contamination. Since the compounds of interest are present only in trace amounts, minor contamination can vitiate the results obtained. "A few milligrams of dust which have fallen on and become mixed with 1 g of meteorite, would significantly alter the original hydrocarbon distribution and introduce contaminations which could be mistaken for indigenous compounds." It is hardly surprising that, although general opinion favours an abiogenic origin for the carbon compounds, definite proof is difficult to find.

The agreement that the 'organised elements' do not reflect indigenous life forms is more firmly based. But as Dr Nagy points out, the danger of judging from morphology alone is that judgement may be affected by context. He recounts: "the author once collected unicellular, blue-green algae, killed them in an organic liquid, made a microscopic preparation, and showed it to an experienced mineralogist whose speciality was meteorites. This scientist identified the dead algae as mineral grains from the Orgueil meteorite."

The second important reason for the attention paid to carbonaceous meteorites stems from the belief that they may contain some of the earliest solid material in the Solar System. The chemical, mineralogical and petrological studies that have been encouraged by this belief are described in detail by Dr Nagy, and take up about a third of the book. In this section, perhaps, the author's approach—"It is *not* the purpose of this book to evaluate the validity of reported findings and theories; the reader will have to do this to his own satisfaction"—works less well. The interpretation of the data is so uncertain that rather more guidance would have been valuable. In all, however, this book provides an eminently useful account of the present state of knowledge of carbonaceous meteorites, and can be recommended as a reference source.

A. J. Meadows

Jurassic environments

Jurassic Environment. (Cambridge Earth Sciences Series.) By A. Hallam. Pp. ix+269. (Cambridge University: Cambridge and London, August 1975.) £11.00.

THE Jurassic System has a special place in geological history as it provided the touchstone for early concepts in stratigraphy and biostratigraphy. Just before he died in 1956, W. J. Arkell, in his *Jurassic Geology of the World*, reviewed the global status of these studies in the final of several of his works which are already, in the best sense, classics of geological literature. The subsequent two decades have been revolutionary ones for the geological sciences, with quite new approaches possible through palaeomagnetism and the concept of seafloor spreading: for the Jurassic, too, substantial work has been done in formerly little known areas. The time may be ripe for a dynamic synthesis on the geography, biogeography and ecology of the period, collating and the interpreting of the changing Jurassic environments.

Over the past two decades Dr Hallam has enlivened Jurassic specialists with a range of novel contributions on various aspects of Jurassic environments, contributions which often emphasised the inadequacies of currently held hypotheses rather more than they provided acceptable explanations of their underlying problems. The stimulating role of these in Jurassic studies, especially to a younger generation, has been considerable. It is therefore particularly welcome to have a summary which brings together his views on the sediments, tectonism, sealevel movements, climate, and biogeography of the period.

The most satisfactory parts of the book are where he attempts a rigorous analysis of Jurassic tectonism, sealevel changes and ammonite provincialism, even if length does not permit an exhaustive treatment. These are marked advances over anything which could have been written twenty years ago. Less satisfactory are the instances, especially in the several chapters on various sediment types, which raise problems common to most geological periods. Here, quixotic tilting at various hypotheses when space is not available to deal thoroughly with any of them is not helpful.

Nonetheless this is a refreshing and valuable contribution for those with any interest at all in the Mesozoic Era. For Jurassic specialists the attempt at updating Arkels work, and the long bibliography of more recent work, will be welcome. Students (if any can afford to buy it) will appreciate the breadth of view presented in a work which will add some sparkle to their labours.

How vividly a comparison of this work with Arkell's 1956 volume brings out contrasts in the scientific approach: Hallam delighting in controversy and speculation, Arkell cautious and scholarly. The one giving a stimulating attack on problems, the other working most to ensure a sound foundation for advance. The writing of the one often repetitive and with printer's errors, that of the other always of systematic and elegant prose. Science uses both, but what would Joscelyn Arkell have thought on the fulsome dedication of a volume to him which spells his name incorrectly even on the dedication page?

M. R. House

Cosmic rays

The Origin of Cosmic Rays. (Nato Advanced Study Institutes Series, Series C.) Edited by J. L. Osborne and A. W. Wolfendale. Pp. x+466. (Reidel: Dordrecht and Boston, Massachusetts, April 1975.) Dfl. 105; £39.50.

Composition of Cosmic Radiation. (Topics in Astrophysics and Space Physics, Vol. 11. By Krishna M. V. Apparao. Pp. x+86. (Gordon and Breach: London, New York and Paris, March 1975.) £5.40.

SPECULATION about the origin of cosmic rays has gone on ever since the discovery of the radiation itself, but in the early stages that speculation was inevitably somewhat wild and unproductive. A quite demoralising lack of hard facts about physical conditions in possible source regions and ignorance about the processes which could occur there gave to the discussions a metaphysical flavour, a tinge of the glamour of the occult, that they have never wholly lost.

But times have changed. Fermi's suggestion, that the particles are accelerated by collisions with moving gas clouds during their zig-zag motion through the magnetic fields of interstellar space, brought the cosmic ray question firmly into the forefront of contemporary astrophysics, and there it has remained. Yet the debate on origins is not over. The Fermi model has given way to others in which supernova explosions, supernova remnants (pulsars) and explosive events in the nuclei of our own and other galaxies have been suggested as cosmic ray sources. The experimental data on which these rival models will be judged is accumulating steadily. There have been spectacular improvements in our knowledge of the chemical composition of cosmic rays, their energy spectra, and their directional properties. Optical and radio astronomy—and, more recently, X-ray and γ-ray astronomy—have provided much relevant information about the physical conditions in regions where acceleration and propagation of cosmic rays must take place.

The meeting organised in Durham last year by Professor Wolfendale and his colleagues, with the financial support of NATO, was planned to consider the origin of cosmic rays in this broad astrophysical context, and it is the proceedings of that meeting which are now available in book form. That publication has taken place in so short a time (less than twelve months) is something of an achievement in itself, and although at first sight the price (verging on £20) must seem high, the book is in truth a veritable bargain. The contributors are authoritative, they have written with the needs of students in mind and not solely for their fellow experts, and the material is as near up-to-date as one could hope for. The known facts about the particle radiations are summarised by Watson (Leeds), Thambyahpillai (London), Rasmussen (Lyngby), and Meyer (Chicago), whereas the related γ radiation is considered by Pinkau (Munich) and Stecker (NASA). Relevant features of galactic structure are described by Osborne (Durham) and Thielheim (Kiel), and the link between the chemical composition of cosmic rays and nuclear processes within stars is discussed by Reeves (Saclay). The arguments in favour of the three major models for cosmic ray acceleration are put forward by their best-known advocates: Burbidge (San Diego), Pacini (Frascati) and Colgate (New Mexico). With such a galaxy of authors, the book will surely become a *vade mecum* for every postgraduate student concerned with astrophysics, and a valued source of reference for others.

The second book under review, on the chemical composition of the cosmic radiation, is a much slimmer volume. The author is, once again, an authority in his field and writes to interest students as well as specialists. In principle, he succeeds. Unfortunately, he has been ill-served by the leisurely pace of book production. Important developments, duly noted in the Durham proceedings, are missing in Dr Apparao's book, which carries as its most up-to-date reference "1971—in the press". Although the book is still of interest and has its uses, the potential purchaser must reflect that the price per page is substantially greater than for the Durham proceedings, and that the information it gives him is three years behind the times.

H. R. Allan

States of matter

States of Matter. (Prentice-Hall Physics Series.) By David L. Goodstein. Pp. xii+500. (Prentice-Hall: Englewood Cliffs, N.J., March 1975.) £12.50.

THIS book is based on lectures given at Caltech as an advanced year-long course in applied physics. It is an outstanding example of the nutritious pabulum fed to American postgraduate scientists, and indeed constitutes a very meaty dish. The first chapter (about 90 pages), based largely as the author indicates on Landau and Lifshitz, provides a rigorous introduction to thermodynamics and statistical mechanics. The following chapters then deal with the perfect gas (40 pages), solids (70 pages), liquids and interacting gases (90 pages), some special states including superfluidity, superconductivity and magnetism (90 pages) and finally critical phenomena and phase transitions including scaling laws (50 pages). Each chapter concludes with some shrewd comments on bibliographical sources and some well-tried, rather demanding examples.

Throughout the book the main themes are tackled in terms of thermodynamics and statistical mechanics. This unified, integrated treatment has many attractive features. It has the disadvantage, however, that in some cases the approach is somewhat tortuous. Again the mathematical analysis is often heavy going and rather formal. On the other hand the accompanying discussion, which is expressed in a verbal rather than a written style is always lively and communicative and reflects a first-hand mastery of the issues under review. Those who find the analysis too tough will always find the author's comments illuminating: they breathe life into the dry bones of the formal analysis and provide a fresh and often entertaining insight into the physics of the problem under discussion. There are also some agreeable personal touches—for example, on quantised entities ending in -ons, such as phonons, photons, and so on. "Even human populations have quantised units called persons." On classical theories: so called not necessarily to distinguish them from quantum mechanical, "but simply because classical is what we usually call the theory that came just before the one we believe now." On the irreversible tendency for entropy to increase he quotes the famous quatrain of Omar Kayyam (" . . . the moving finger . . . ") with the comment that "there have been many other statements of the Second Law, all of them less elegant."

The chapter on liquids, fascinating as it is, probably provides material least familiar to the student, and the physics seems to be overlaid too heavily with computational tricks for calculating the interaction of atomic clusters. Again the inadequacy of pairwise additivity could have been made more concrete if the author had compared, for example, the lattice energy of solid argon with that deduced from pairwise calculations: and if his fifth chapter had dealt with dielectrics (as well as magnetism) he could have linked the problem of additivity with the dielectric properties of matter in the condensed state. This in turn provides a bridge with the van der Waals' properties of liquids and solids. Finally, the author quotes the opinion of some scientists that plasmas constitute the fourth state of matter: it would do no harm if applied physicists were to be taught instead about the colloidal state. This is not only of great importance, it also offers scope for some very nice physics. But these are personal opinions rather than criticisms.

Dr Goodstein's heroes, to judge from his references and comments, are Landau and Lifshitz, Mott and Jones, G. I. Taylor and Galileo Galilei. This fine sense of scientific discrimination and catholicity of interests characterise the stimulating and challenging book he has written.

David Tabor

Aged Ecuadoreans

Michaela Mendieta Quesada, aged 106

The Centenarians of the Andes. By David Davies. Pp. 128+17 photographs. (Barrie and Jenkins: London, July 1975.) £3.95.

POPULATIONS containing numerous centenarians and supercentenarians have been reputed to exist in the Ecuadorean Andes since 1825 (G. Coggeshall, 1825, *Voyages to various parts of the world*), and have recently been noted by Leaf (*Youth in old age*, 1975). This book is an anecdotal but informative study of the distribution, way of life and documentary authenticity of centenarians in Vilcabamba, who have been fairly extensively studied, at least from the standpoint of documentation by Dr Miguel Salvador for the Ecuadorean Government. Ages of 140 and 150 years have been reported, but equally remarkable is the state of physical preservation of people throughout old age. Dr Davies' book contains no demographic tables, so that the population breakdown cannot be ascertained from it. As in Abkhasia, interest naturally focusses on the authenticity of the high age records—these seem better documented than in Abkhasian Muslims, by reason of the care devoted to Catholic birth and burial registers.

At present the high age population seems to be confined to a small enclave of mountain villages, but there are rumours of similar longevity in other parts of the Andes not yet investigated. In the villages around Vilcabamba longevity seems to affect at least three distinct population types. Possible causes of survival (genetic endowment, hybrid vigour, low calorie or low fat diet, particular dietary constituents, environment, and absence of psychosocial pressure to age) are discussed, but there is as yet no evidence to support any one of these factors, except perhaps isolation from viruses and continued acceptance of 'old' activity, which clearly operates in the field of work and of sexuality. The environment but not the diet resembles that of Abkhasia, where longevity is reportedly geographic rather than specifically ethnic, affecting Russians, Abkhases and Jews who live in the area.

Dr Davies' treatment is of necessity that of a travelogue, illustrated with some good photographs. A proper monograph giving the demographic picture and the true prevalence of centenarism is overdue, and it is to be hoped, in view of the great interest of the model, that Dr Salvador and the Ecuadorean Government will provide us with one to amplify a previously circulated report (M. Salvador, *et al.*, 1972. *Vilcabamba, tierra de longevos*, Quito: Casa de la Cultura Ecuatorian).

Alex Comfort

Aspects of oceanography

Introduction to Marine Geology and Geomorphology. By Cuchlaine A. M. King. Pp. 309. (Edward Arnold: London, 1975.) £9.90.

Introduction to Physical and Biological Oceanography. By Cuchlaine A. M. King. Pp. 372 (Edward Arnold: London, June 1975.) Boards £11; Paper £5.50.

OCEANOGRAPHY has progressed in the last decade to an even greater extent than most sciences. This is reflected in the fact that Professor King when preparing a second edition of his well-known textbook *Oceanography for Geographers* found it necessary to divide it into two volumes. The first of these deals with marine geology and geomorphology. The book commences with an introductory chapter, which skimpily covers topics as various as deep-sea sediment sampling, diving, station fixing and ocean resources. It continues with a chapter on the structure of the ocean basins in which rather restricted coverage is given to ocean spreading and plate tectonics. The next two chapters, which deal with the continental margins and the morphology of the open sea are very good and probably the most useful in the book. The fifth chapter deals with deep-sea and near-shore sediments and their rates and mechanisms of formation; there is, regrettably, little on their chemistry.

The book closes with a chapter on the origin of ocean water and changes in sea level; the treatment of the former is extremely perfunctory, and no mention is made of the origin of the dissolved solids which give seawater its special character. In general, although some effort has been made to include recent work, this has been done in a rather unselective way. It is particularly disappointing to find no discussion of the results obtained during the Deep-Sea Drilling Program as this has done so much to revolutionise our ideas on marine geology and sedimentology. Although this book can be recommended for students of geography requiring an introduction to marine geomorphology, it is likely to be of much less value to those seeking background reading in marine geology, because of its superficial treatment of the subject.

The second book is an uneasy union between physical and biological oceanography It commences with an introductory chapter which does not relate well with the following chapters and the purpose of which is obscure, particularly when related to chapter 8. Then follow chapters on physical oceanography dealing with the waters of the ocean and their circulation, tides and waves. Much of it is dealt with in a purely descriptive fashion. On the occasions, particularly in chapter 3, when explanations of physical phenomena are offered they are often garbled to such an extent as to suggest a basic lack of understanding on the part of the author (for example, the first complete paragraph on page 141 and the first three paragraphs on page 68 on westward intensification). There are also a number of unjustifiably bold statements of "fact". Thus, the tsunami wavelength (not a well-defined quantity) is stated to be 900 km on page 8 and 160 km on page 9, but surely not in Loch Lomond (page 190). The discussion of the heat budget on page 30, based on work done in 1936, makes no mention of the fact that the individual contributions to it are still not known with any accuracy. On page 33 the impression is given that the only minor elements present in sea water are silver, gold and radium.

The book is out of date in a number of important respects; thus, in chapter 5 the discussion on the observed wind-wave spectrum makes no mention of JONSWAP and the Pierson–Moskowitz spectrum; nor are the currently accepted ideas on longshore and rip currents presented. In many instances important terms are left undefined and even undescribed (for example, PCB, Coriolis force, primary production, and salinity, the latter being only related to chlorinity (itself undefined) by an out of date formula). The text is strewn with minor undefined terms, of which there are six examples in the first paragraph on page 141.

The next two chapters consisting of 94 pages in all, are concerned with biological matters. The first of them deals in a very disjointed way with marine production at all trophic levels. In spite of its key importance primary production is dismissed in about 6 pages. The following chapter deals with the biological exploitation of the ocean, and is primarily a scrappy account of fishing and whaling. The final chapter on "Uses and problems of the oceans", includes subjects as diverse as oceanic pollution, conservation and law of the sea. The author's literary style is an awkward one, and occasionally sentences have to be read several times before they can be understood. Although this book may perhaps be of value for geographers, in the reviewer's opinion it has little to offer to prospective oceanographers or marine biologists, because of its superficiality.

J. P. Riley

Materials and Technology

The publication of Volume 8 in September 1975 sees the completion of this systematic encyclopedia which has been produced for people who want to know about materials, including those who have no advanced training in science or technology. Within each volume each chapter has been written by a specialist or a group of specialists so as to represent a comprehensive account of the subject, which will be of use not only to the general reader but also to those who work with materials in their professional capacity. It will also fulfill a useful function in education as a link between formal textbooks and the practical application of academic learning.

Volumes are:

Air, water, inorganic chemicals and nucleonics
Non-metallic ores, silicate industries and solid mineral fuels
Metals and ores
Petroleum and organic chemicals
Natural organic materials and related synthetic products
Wood, paper, textiles, plastics and photographic materials
Vegetable food products and luxuries
Edible oils and fats, animal food products, and material resources: general index.

Each volume is priced at £20.00 but there is a reduction of £2.00 per volume on all orders for the complete set.

We have produced a 16 page brochure on *Materials and Technology* which includes full details of the contents of each volume. If you would like to receive this please write to:
Room 504, Longman House,
Burnt Mill, Harlow,
Essex CM20 2JE.

review article

Mammalian plasma membranes

Mark S. Bretscher* & Martin C. Raff†

1975 is the fiftieth anniversary of the proposal, by Gorter and Grendel, that biological membranes are based on a lipid bilayer. Now well-established, this proposal, like the DNA double helix, was a major breakthrough in molecular cell biology. Here we discuss current concepts about the molecular composition, organisation and behaviour of the plasma membranes of mammalian erythrocytes and nucleated cells.

CELL membrane structure and function are intimately linked to each other and to much of biology. The plasma membrane is the most experimentally accessible and, in many respects, the most important of the cell's membranes It maintains the internal milieu of the cell and has a vital role in intercellular communication. In this overview, we discuss the general features of normal mammalian plasma membrane architecture and behaviour that have been gleaned from recent experiments on lipid bilayers; erythrocyte ghosts and nucleated cells

The lipid bilayer

The three classes of lipids in cell membranes, phospholipids (which comprise the majority), neutral lipids (mainly cholesterol), and glycolipids (largely glycosphingolipids), usually constitute almost half the plasma membrane mass. They are all amphipathic, having a hydrophilic (polar) and hydrophobic (non-polar) end. Phospholipid molecules have a polar head group and two hydrophobic hydrocarbon tails of variable lengths and degrees of unsaturation; when placed in an aqueous environment they spontaneously form bilayers, burying their tails and leaving the head groups exposed to water. Low angle X-ray diffraction studies of various membranes show that the bulk of the phospholipids in these membranes are arranged in the form of a bilayer[1]; this provides the structural framework of the membrane[1-3].

An important advance in understanding membrane structure has come from studies of the physical properties of lipid molecules in synthetic bilayers and selected biological membranes. A variety of techniques, including nuclear magnetic and electron spin resonance, have been used to measure the motion of individual lipid molecules or their different parts[2-4]. These show that lipid molecules in artificial bilayers readily exchange places with their neighbours in their own monolayer[5], but very rarely migrate from one monolayer to the other[6], a process called "flip-flop". Thus, lateral diffusion of a lipid is rapid, each molecule exchanging with its neighbour about 10^6 times a second (ref. 7); in contrast, neighbour exchange across the bilayer by flip-flop occurs less than once a fortnight[8,9]. Nor are individual lipid molecules rigid; their hydrocarbon chains flex and the degree of flexion may be greatest near the centre of the bilayer and least adjacent to the polar head group[10]. Thus the lipid component of a membrane is a two-dimensional liquid in which molecules are restricted to their own monolayer.

The fluidity of a bilayer at a given temperature is determined by its composition. An artificial bilayer of a single type of phospholipid (such as dipalmitoyl phosphatidyl choline) has a sharp and characteristic melting point (or phase transition) at which it changes from its liquid state to a rigid crystalline bilayer (or gel phase)[4] This temperature depends on the nature of the phospholipid head group and on the length and degree of saturation of the hydrocarbon side chains; as might be expected, a high melting temperature is found for lipids with long hydrocarbon chains, whereas the introduction of *cis*-double bonds into these chains (which makes them difficult to pack next to each other) leads to a low melting temperature In artificial bilayers containing a mixture of phospholipids there is a progressive phase change over a broad temperature range, indicating that a "phase separation" into clusters of gel and liquid occurs[4,11].

When cholesterol is introduced into a bilayer, the plate-like steroid rings interact with, and partly immobilise, those regions of the hydrocarbon chains closest to the polar head group (leaving the rest of the paraffin chains flexible); this prevents their crystallisation[4]. Thus, in high concentration, cholesterol abolishes temperature-induced phase transitions; it has the dual effect of preventing formation of crystalline gel areas while inhibiting the overall flexing motion of the hydrocarbon chains. In this way, it imparts an "intermediate fluid condition" to the interior of the bilayer[4].

In thinking about plasma membrane lipids, it is often helpful to draw an analogy between them (as two-dimensional solvents) and water (as a three-dimensional solvent). For example, we may wonder why mammalian plasma membranes contain a variety of phospholipids having different head groups, such as phosphatidyl choline, phosphatidyl ethanolamine and phosphatidyl serine In part, this may be because some membrane enzymes need specific phospholipids for normal function[12,13] It is well known that water-soluble enzymes often require a particular ion for activity and, in a similar way, a membrane enzyme may require an adjacent ethanolamine (rather than serine) head group as activator. Since the bilayer is a liquid, an individual phospholipid molecule could activate several different membrane enzymes over a period of time, just as an ion could for soluble enzymes It has been reported that proteins

---

† Medical Research Council Neuroimmunology Project, Department of Zoology, University College London, Gower Street, London WC1E 6BT, UK.

which penetrate into the lipid bilayer tend to immobilise a collar of surrounding lipid molecules ("boundary lipid")[11,12,14,15]. This is comparable with the tendency of water molecules to exist in an ordered state around the surface of water-soluble proteins.

In mammalian plasma membranes, phospholipid heterogeneity and the presence of cholesterol and protein thus modulate the fluidity of the bilayer. The biological importance of membrane fluidity is suggested by the fact that yeast, bacteria and various poikilothermic organisms change their membrane lipid composition to maintain a relatively constant fluidity in the face of changes in temperature[16,17].

There is increasing evidence for significant asymmetry between the inner and outer leaflets of the lipid bilayer of human erythrocytes. Glycolipids seem to be confined to the outer half of the bilayer[18], and radiolabelling[19,20] and phospholipase-mediated digestion studies[21] indicate that most of the choline-containing phospholipids (phosphatidyl choline and sphingomyelin) are found in the outer half of the bilayer, while the amino phospholipids (phosphatidyl serine and phosphatidyl ethanolamine) are largely confined to the inner half. Since the former lipids are more saturated than the latter, head group asymmetry implies asymmetry in the hydrocarbon tails as well; and because only phosphatidyl serine carries a net negative charge, whereas the other phospholipids are zwitterionic at physiological *p*H, there is also a charge asymmetry between the monolayers. Although it is not known whether lipid asymmetry exists in other cell membranes, there is increasing evidence that it does. Since phospholipids do not spontaneously flip-flop at an appreciable rate, it seems likely that the asymmetry arises during biosynthesis[20]. Its biological significance is unknown.

The relationship between the lipids in different membranes of a cell is obscure. Although all membranes can deacylate and reacylate their own phospholipids, only the endoplasmic reticulum has the enzymes required for *de novo* phospholipid synthesis[22], which suggests that phospholipids are synthesised and inserted into pre-existing membrane there. Furthermore, specific proteins in the cytosol exchange phospholipids between the different membrane compartments[22], but how the observed differences in lipid composition between organelles within a cell are generated or maintained is unknown. In erythrocytes, where *de novo* lipid synthesis does not occur, there is a slow renewal and remodelling of cellular phospholipids through exchange with plasma lipids[23]. It is not clear to what extent such exchange occurs in other cells, but most cells seem able to incorporate exogenous glycolipids into their surface membranes[24].

There remains a number of unresolved questions about membrane lipids which could have important implications for membrane function. For example, it is often assumed that each lipid monolayer of a membrane is under the same lateral pressure, but this need not be so. It seems quite possible that the external monolayer is under compression and the inner monolayer under tension. Such an arrangement can be visualised if we think of an area of bilayer with more phospholipids on one side than on the other, but in which each monolayer covers the same area. This is possible because lipids are rather elastic to lateral compression Again, it is unclear to what extent there is compositional or conformational (liquid against gel) heterogeneity within each monolayer, and whether such heterogeneity would have biological significance. A change in lipid conformation can lead to a change in protein distribution in reconstituted membranes[11], but it seems doubtful that membrane protein distribution or function is ever normally controlled by changes in lipid conformation.

Finally, the widespread occurrence of many different glycolipids should be mentioned. In general, their biological function is obscure, although some of the gangliosides have been implicated as receptors for some bacterial exotoxins, such as cholera[24,25] and tetanus[25].

Association of membrane proteins with the bilayer

More than half the mass of most plasma membranes is protein. Unlike the extended monolayer of protein on both surfaces of a membrane originally envisaged[3], membrane proteins seem to be built into the lipid bilayer in a highly asymmetrical way. The ease with which these proteins can be removed from the membrane varies over a more or less continuous spectrum—from those which can be eluted by rather gentle procedures (such as lowering the ionic strength) to those which can only be removed by total disruption of the bilayer matrix. The two extreme cases are sometimes referred to as "peripheral" or "extrinsic" and "integral" or "intrinsic" proteins[26]. In a loose sense, this classification may be helpful, provided that it is not mistaken for a molecular description of how these proteins are arranged in their membranes, which, in almost all cases, is unknown. Some proteins extend across the bilayer; these are believed to have hydrophobic surfaces which associate with lipid molecules by hydrophobic interactions in the bilayer interior. To solubilise them, detergents, organic solvents or chaotropic agents are needed which break hydrophobic bonds and destroy the bilayer; even then, some strongly associated lipid may remain. Detergents, like membrane lipids, are amphipathic; they can be anionic (as with sodium dodecyl sulphate (SDS), deoxycholate (DOC), or Sarcosyl), catonic (such as Cetavlon) or non-ionic (as with the Triton, Brij and Tween detergents, Lubrol PX, Nonidet P40). Their hydrophobic ends bind to the hydrophobic regions of the proteins, largely replacing the phospholipid, and thus bring the proteins into solution as detergent–protein complexes[27]. In some cases, the detergent (such as SDS) also binds to hydrophilic regions of the protein, causing them to unfold. Even with non-denaturing detergents, if the detergent (and remaining lipid) is removed, membrane proteins are often highly insoluble and aggregate in neutral aqueous buffers.

Membrane biochemistry has been revolutionised by the use of electrophoresis in SDS polyacrylamide gels; to separate and study solubilised membrane proteins. In this procedure, the amount of anionic SDS bound is approximately proportional to the mass of the polypeptide. The charge of the detergent overwhelms the intrinsic charge of the protein, which thus migrates according to its molecular weight when sieved by the polyacrylamide; it can later be visualised by various protein stains. Although glycoproteins can also be resolved by this technique, estimating their molecular weights from their electrophoretic mobility is misleading if they contain large amounts of carbohydrate, because the amount of SDS bound per unit mass of glycoprotein, and the hydrodynamic behaviour of the detergent–protein complex, are altered[20,28].

Membrane proteins of erythrocytes

More is known about the plasma membrane of human erythrocytes than about that of any other mammalian cell, mainly because it is the only membrane in these cells and can be readily isolated intact, free from contamination by other cells or organelles. Erythrocyte membranes, or "ghosts", are prepared by hypotonic lysis of red cells, which releases the haemoglobin. By studying intact cells, permeable (unsealed) ghosts, or inside-out resealed ghosts[29], one can study both the external and cytoplasmic faces of the membrane.

When human erythrocyte membrane proteins are studied by SDS polyacrylamide gel electrophoresis, approximately 15 major protein bands are seen, varying in molecular weight from 15,000 to 250,000. The properties of these proteins have been frequently reviewed[20,29–31], so they will not be discussed in detail here. Several important general points have, however, emerged from studies using labelling reagents or proteolytic enzymes to detect which proteins are accessible on one or other (or both) membrane surface(s). (1) All of the proteins and glycoproteins are asymmetrically oriented across the bilayer, being exposed on one or both sides of the membrane. (2) Most of the protein molecules are associated with the cytoplasmic side of the membrane, and of these, most can be removed from the membrane in very low ionic strength solutions. The most abundant protein located on the cytoplasmic side is "Tektin A" (ref. 32) or "spectrin", a fibrous protein which comprises about 25% of the membrane protein mass and which is composed of two separable polypeptides (about 220,000 and 240,000 daltons each). (3) There are two major proteins exposed on the external surface; both are glycoproteins which extend to the cytoplasmic surface and thus span the membrane No protein is found associated only with the external surface of the cell. The larger of the two proteins which span the bilayer (electrophoretic band 3) (ref. 29) is a globular protein of about 100,000 daltons; it has relatively little carbohydrate (but may be a receptor for concanavalin A) (ref 33), and may be present in the membrane as a dimer. This protein is believed to be the red cell anion and glucose channel[20,34,35]. The other (MN glycoprotein=major sialoglycoprotein=glycophorin) is the most completely characterised mammalian plasma membrane protein; it is 131 amino acids long and has a molecular weight of approximately 30,000 (refs 31 and 36). Its amino-terminal hydrophilic end at the cell surface carries all of the carbohydrate (about 100 sugar residues), accounting for the great majority of the cell surface carbohydrate, including more than 90% of the sialic acid, and thus most of the negative charge of the cell surface. Its hydrophilic C-terminal tail is exposed on the cytoplasmic side, while an α-helical hydrophobic segment of 23 amino acid residues spans the non-polar bilayer. This glycoprotein carries some blood group alloantigens (MN, possibly ABO) and acts as a receptor for influenza virus and some plant lectins (PHA, wheat germ agglutinin)[31]. Besides these major proteins, a number of membrane-bound enzymes are present in such small amounts that they do not show up as distinct bands on gels; nonetheless, it seems from functional studies that some of these also are situated asymmetrically across the bilayer[29].

At present, freeze fracture electron microscopy is the only way of visualising the interior of a cell membrane. In this process cells are fractured while frozen in a small block of ice. The fracture plane passes through the middle of the bilayer[37], exposing two complementary fracture faces, which are shadowed with platinum and carbon. The resulting replicas, examined in an electron microscope, reveal that the inner (A) and outer (B) halves of the erythrocyte bilayer are studded with small (80 Å) intramembrane particles. These are homogeneous in size and randomly distributed, being more dense on the inner (A) face. Since lipid bilayers and vesicles are devoid of particles unless proteins are included, the particles probably consist mainly of protein. It is likely that to be visualised as a particle, a polypeptide, either by itself, or as part of a subunit aggregate, must span the membrane and be of sufficient size to "cast a shadow" Although it is unproven which proteins constitute the particles in human erythrocytes, much of the evidence is consistent with contributions both from band 3 and from the MN glycoprotein. Thus, when erythrocyte ghost particles are induced to aggregate into clusters (see below), cell surface ABO antigens[38], receptors for the lectins, PHA[39] and concanavalin A[40], and for influenza virus[39] are aggregated in the same pattern as the particles. This suggests that the particles extend to the outer surface of the ghost membrane, and that most are constituted by the two major surface-exposed proteins that are thought to carry these antigens and receptors.

The principal surface-exposed proteins of erythrocytes seem to be relatively immobile[41], and in this respect differ from those of nucleated mammalian cells, in which many of the plasma membrane proteins are able to move about in the plane of the membrane. There is increasing evidence that spectrin forms a filamentous network on the cytoplasmic surface of the erythrocyte membrane and it is this that directly or indirectly holds the particles, and thus the major penetrating proteins that probably constitute them, in place[42]. Thus, intramembrane particles can be induced to aggregate in ghosts in a variety of conditions, but only in ghosts which have been depleted of spectrin; particle aggregation does not readily occur in intact erythrocytes, or in ghosts having a full complement of spectrin[42]. It is not known whether the various minor erythrocyte membrane proteins, such as Na^+–K^+ ATPase or acetylcholinesterase, are capable of translational mobility, or whether they, too, are immobile.

Membrane proteins of nucleated cells

The total membrane mass in nucleated cells includes nuclear, endoplasmic reticulum, Golgi, mitochondrial and various vesicle membranes. The plasma membrane can therefore be studied only after its isolation from these other membranes, or by using membrane-impermeable reagents to label surface proteins. Moreover, reliable methods for making the equivalent of permeable or inside-out ghosts to study the cytoplasmic side of these membranes are still lacking, although isolated phagosomes may well prove useful in this respect[43]. Thus, while it seems likely that a larger variety of membrane proteins and glycoproteins will be found in most nucleated cells than in erythrocytes, little is known about their topographical arrangement in the membrane One very large glycoprotein of cultured fibroblasts has, however, attracted considerable attention[44]. It seems to have a molecular weight of about 250,000 and is accessible to the cell exterior, since it is extremely labile when intact cells are treated with low levels of trypsin. This protein is also sensitive to proteolytic attack from the cytoplasmic side of the membrane (in phagosomes, which contain an inverted region of plasma membrane) and thus probably spans the fibroblast plasma membrane[43]. The great interest in this molecule resides in the observation[44] that it is absent from the plasma membrane of a variety of virally-transformed fibroblasts, which suggests that it may have a role in the control of cell growth.

Perhaps the most important recent discovery about the plasma membrane of nucleated cells is that many of its proteins are mobile, being able to diffuse laterally in the plane of the membrane, and, by analogy with rhodopsin molecules in retinal rod disk membranes[45], to rotate about an axis perpendicular to the membrane plane. The first suggestion of this came from X-ray diffraction studies on rod disk membranes, which indicated that rhodopsin molecules, the major proteins in these membranes, were mobile and in a "liquid" state[46]. The dramatic demonstration, in 1970, that different antigens on the surfaces of nucleated mouse cells and human cells rapidly intermix when the cells are fused by inactivated Sendai virus was the first indication that proteins in the plasma membrane had considerable mobility[47] The following year, it was demonstrated that divalent antibodies, binding to immunoglobulin receptors, or to other antigens on the surface of lymphocytes, lead to the selective redistribution of the antibody–antigen complexes in the plane of the membrane[48]. Three distinct types of redistribution occur. (1) Patch formation, which is the passive clustering of cross-linked macromolecules into aggregates, a process analogous to a precipitation or agglutination reaction occurring in the two dimensions of the fluid membrane[49]. (2) Cap formation, the polar segregation of the cross-linked molecules from other membrane components by an active process, probably dependent on microfilaments[48,50]. (3) Pinocytosis of the complexes, which in some cases may lead to extensive loss of the membrane protein[48,50], a phenomenon referred to as "antigenic modulation"[51] In some systems, shedding of the surface antigen–antibody complexes may contribute to modulation. Moreover, monovalent Fab fragments of antibodies can, in some situations, induce pinocytosis[49] and/or modulation[51]. Hormone-induced disappearance of cell surface hormone receptors, referred to as "down regulation"[52], presumably represents another example of ligand-induced modulation. In each case, the process is reversible: the cells resynthesising the modulated protein when incubated in the absence of ligand. It is likely that modulation represents a normal homeostatic mechanism whereby the concentration of signalling ligand regulates the concentration of its receptors on a target surface.

Patching and pinocytosis can be induced in all nucleated mammalian cells so far studied, if an appropriate cross-linking agent is used, while capping has been demonstrated in many (but not all) cell types, including lymphocytes, granulocytes, and fibroblasts. Besides providing direct evidence for membrane protein mobility, ligand-induced redistribution is a powerful tool for mapping cell membranes. For example, it is possible to determine the relationship between two molecules, A and B, on the surface of a cell by redistributing A with anti-A antibody and seeing what happens to B, if B redistributes with A, the two molecules are associated in the membrane (or become associated after ligand binding), whereas, if B is left behind, they are independent. The two antibodies are followed by conjugating them with different markers, such as fluorescein and rhodamine. By such "cocapping" experiments, it has been shown that the major histocompatibility loci in man (referred to as HLA–A, HLA–B and HLA–C)[53] and mouse (H–2K and H–2D)[54] code for independent membrane glycoproteins (present on virtually all cells) which are associated with β_2-microglobulin[55] The great majority of macromolecules that have been studied[48,53,54] cap independently, which implies the absence of stable long range ordering of these membrane macromolecules. Moreover, when ligand-induced redistribution is avoided, ultrastructural mapping studies, using ferritin-conjugated antibodies and lectins, generally show a diffuse distribution of antigens and lectin receptors on lymphocytes[56] and other dissociated cells

On the other hand, on cells interacting with each other in tissues or in culture, there is in many cases an uneven distribution of plasma membrane proteins In epithelial cells, certain plasma membrane transport sites[57] and other membrane enzymes[58] are restricted to only one surface of the cell, although they are presumably able to diffuse over large areas of the membrane in which they are confined. More severe restriction of movement exists in the case of gap junctions—those points at which cells in tissues or in culture are ionically (electrically) and metabolically coupled. These junctions are seen in freeze fracture microscopy[59] as polygonal arrays of intramembrane particles; they presumably arise from randomly distributed units in each cell membrane which become highly ordered on cell contact One of the most striking cases of immobile surface proteins is the acetylcholine receptor of the neuromuscular junction. These molecules are confined to the area of the endplate in inervated striated muscle and probably remain fixed even after denervation[60]. The metabolic turnover of gap junction proteins[61] and junctional acetylcholine receptors[62] is extremely slow compared with the turnover of most other membrane proteins[61,63]. This suggests, perhaps, that immobile proteins may be the most stable class of membrane protein.

Although it is unkown how the polarity of epithelial cells is generated, or how junctional acetylcholine receptors are held in place, in principle there are several means by which the distribution and movement of membrane proteins might be controlled These include the formation of large aggregates of protein which could diffuse only very slowly, as is the case in the purple membrane of *Halobacterium halobium*, which is a planar crystalline lattice of membrane proteins[64], and tethering membrane proteins from outside the cell by external fibrous proteins[44], or by cell–cell contact, as in gap junctions.

A quite different mechanism for controlling the distribution and movement of cell surface proteins became apparent with the discovery of antibody-induced capping of surface antigens. The process of capping, and probably also cell locomotion over a surface, involves the directional movement of cross-linked proteins in the membrane whilst allowing free movement of other proteins. Recent evidence suggests that, during capping, those surface proteins which are moved, are tethered to a cytoplasmic matrix which includes microfilaments and possibly microtubules.

Intracellular fibrillar structures in nucleated cells

The three main types of intracellular fibrillar structure seen by electron microscopy in most nucleated mammalian cells are microtubules, microfilaments and intermediate filaments

Microtubules[65], are large, rigid, cylindrical molecules built from a protein subunit called tubulin. Each tubule is composed of 13 parallel 50-Å filaments arranged as a tube of variable length around a hollow 150-Å core. They often form an interconnected cytoskeletal network (through their attachment to centrioles) in the cytoplasm of most mammalian nucleated cells. They are also present in cilia, flagella, and sperm tails where they help produce the motion of those organelles, and in mitotic spindles where they help move chromosomes during mitosis. Cytoplasmic microtubules are usually in a state of rapid assembly and disassembly, processes whose control is still unclear, although Ca^{2+} (ref. 65) and the cyclic nucleotides[66,67] may be involved They can be induced to dissociate by pressure and by cold, and their assembly is inhibited by certain plant alkaloids (such as colchicine and vinblastine) which bind with high affinity to tubulin. Evidence suggests that cytoplasmic microtubules may be involved in controlling membrane protein movement and distribution. For example, the binding of concanavalin A (con A) to specific sugar residues on a cell is known to inhibit antibody-induced redistribution of various cell membrane antigens; this inhibition can be relieved by manoeuvres that disrupt microtubules[68]. This observation has been taken to indicate that many different membrane glycoproteins are linked to the microtubule system[68] As con A is known to bind to a heterogeneous population of membrane glycoproteins, however, it seems possible that it inhibits the movement of otherwise unrestricted lectin receptors by cross-linking them to a subclass of con A-binding glycoproteins which are fixed to the microtubule system[69] Since microtubules as seen by electron microscopy do not interact directly with the plasma membrane of most mammalian cells, their influence on membrane proteins must be indirect, perhaps through microfilaments.

Microfilaments[70] are seen in all nucleated cells as fine filamentous structures with a diameter of about 50 Å. They can be decorated with muscle heavy meromyosin (the active head part of myosin)[70], or with fluorescent anti-actin antibody[71]; this, together with studies on isolated microfilaments, shows that they are made of subunits very similar, if not identical, to skeletal muscle actin. In the cell they are associated with cytoplasmic myosin[72] and tropomyosin[73]. Microfilaments seem to exist as at least two distinguishable species: "lattice microfilaments", which form a loose network of short, interconnected filaments which may be associated with the cytoplasmic side of plasma membranes and which seem to be sensitive to the drug cytochalasin B, and "sheath" or "stress" microfilaments (also called "actin cables")[71] which exist as bundles of fibres running beneath the plasma membrane, often parallel to the long axis of fibroblastic cells. These bundles of microfilaments appear to be less sensitive to cytochalasin B (ref. 70). It is likely that both types of microfilaments are contractile, and collectively have an important muscle-like role in cytoplasmic streaming, various forms of plasma membrane movement, in cell shape changes and locomotion Their possible function in regulating membrane protein mobility is suggested by the demonstration that cytochalasin B (in conditions where its effects on membrane transport are minimised) completely inhibits concanavalin A-induced capping of con A-binding sites on lymphocytes and enables preformed caps to disperse[69]. This suggests that lattice microfilaments have an important role in the capping process, and also in holding the cap at the tail of the cell. There is a hint that, in some circumstances, microfilaments and microtubules may act synergistically in lymphocyte capping; microtubule-disrupting drugs alone do not inhibit capping of immunoglobulin by anti-immunoglobulin antibodies on mouse lymphocytes, and it is only partly inhibited by cytochalasin B (ref. 48), but when cytochalasin B and drugs which disrupt microtubules are used together, they completely inhibit and partly reverse immunoglobulin capping[69] Although caution is required in interpreting these drug effects, it seems likely that microtubular and microfilament networks can cooperate with each other, the former (possibly together with sheath microfilaments) perhaps providing a structural framework relative to which lattice microfilaments and membrane macromolecules can be displaced.

Intermediate filaments[74] are approximately 100 Å in diameter. In neurones they are known as neurofilaments but similar filaments are found in most mammalian cells, often intermingled with microtubules. Their chemistry and function are unknown, and no specific reagents have been shown to disrupt them. Tonofilaments are of similar diameter and are found attached to the plasma membrane of epithelial cells at specialised sites called desmosomes.

At present, the intense interest in these intracellular fibrous proteins is aimed at understanding their structure and function. One would like to know the nature and extent of their heterogeneity and interactions, how they interact with cell membranes, and the factors that control their orientation within the cell, their assembly and disassembly.

Intramembrane particles in nucleated cell plasma membranes

In nucleated mammalian cells, such as lymphocytes or fibroblasts, freeze fracture electron microscopy reveals intramembrane particles more heterogeneous in size and less densely distributed than in erythrocytes This greater heterogeneity presumably reflects the large variety of globular proteins in, and thus the greater biochemical complexity of, these membranes. Furthermore, unlike in erythrocytes, most attempts to demonstrate a relationship between the particles and specific cell surface receptors and antigens have failed. Thus, when surface antigens or lectin receptors are capped on lymphocytes[75], or when lymphocyte surface proteins are covalently labelled with haptenic groups and these are capped with anti-hapten antibody[76], no equivalent redistribution of the intramembrane particles is seen. Moreover, when lymphocytes or fibroblasts are exposed to high concentrations of glycerol, which reversibly aggregates the particles in these cells[77], no concomitant aggregation of con A–ferritin-binding sites is seen by electron microscopy (N. B. Gilula, D. Lawson and M C R., unpublished). Thus, it seems that the majority of proteins on the surface of these cells that bind antibodies or lectins, or that can be readily haptenised, are not associated with the particles.

This inability to identify particles with external receptors and antigens probably results from the existence of two different classes of surface proteins in nucleated cells Both may span the plasma membrane, but they are otherwise distinguished in the following ways. One group has an extensive region of the polypeptide and attached oligosaccharide exposed on the outer surface of the cell but little mass in the plane of the bilayer, as in the case of the erythrocyte MN glycoprotein. These surface components would be expected to bind ligands well, but, by themselves, would not be seen in the freeze fracture plane because their intramembrane mass is too small. What happens to such a protein during freeze cleavage? Either one or other region of the polypeptide chain on either side of the membrane pulls out of the ice with which it is in contact, or covalent bonds in the protein are broken. Something must give. For example, it is known that in Semliki Forest virus the spike proteins span the viral membrane[78], yet no particles are seen in the fracture plane It seems possible that in this case, and possibly many others, the covalent backbone of that region of the protein inside the membrane has been ruptured. Proteins of the other class are globular, have most of their mass in the plane of the membrane and thus are seen as particles, but do not extend appreciably outside the external surface of the plasma membrane bilayer and are therefore rather inaccessible to ligands. The major erythrocyte protein (of 100,000 daltons, band 3) seems to have these properties; it is remarkably unreactive on its external surface[20] and would thus be difficult to haptenise. In other plasma membranes, haptenisation of similar globular proteins may also prove to be difficult; an attempt to aggregate them by anti-hapten antibody might therefore be unsuccessful and leave them (and thus the particles) unmoved. It seems likely that this latter class of globular membrane protein would include the many proteins involved in the active and passive transport of small molecules (such as ions, sugars, nucleosides and amino acids) and in the formation of cell junctions.

Most of the globular proteins associated with transmembrane functions are difficult to purify and study biochemically. The great value of the freeze fracture technique is that it shows us the distribution of these proteins in the plane of the membrane with remarkable clarity. What would improve its power enormously would be some general method for relating components, identified either as a band on a gel or by serological methods, to the particles seen in the freeze fracture plane of a membrane. Freeze fracture autoradiography and defining particle subclasses by improved shadowing techniques should prove extremely useful in this respect (D Branton, personal communication).

Membrane carbohydrate

The proportion of carbohydrate in plasma membranes is never more than 10% by mass and often much less. It is present mainly as oligosaccharide side chains covalently attached to proteins and, to a lesser extent, sphingolipids. Although more than one hundred different monosaccharides are found in nature, only about ten occur in membrane glycoproteins and glycolipids, the principal sugars are galactose, mannose, fucose, galactosamine, glucosamine, glucose and sialic acid[79], the last usually being terminal and the chief contributor to the net negative surface charge carried by all mammalian cells Glycolipids and glycoproteins contain similar sugars, except that in glycolipids, mannose is generally absent and glucose is usually found as the first sugar linked to lipid The oligosaccharide side chains of membrane glycoproteins, and of a small number of glycolipids, can be remarkably complex Although they are rarely more than 15 sugar residues long, they are usually branched, and can be bonded together in a variety of different linkages[79]. This could give rise to a great range of structures so that, for example, three different sugar molecules can be arranged into hundreds of different trisaccharides. Although substantial progress has been made in elucidating the sequences of many oligosaccharides bound to lipid or protein, the biological functions of the carbohydrate remain obscure. In both internal and plasma membranes the carbohydrate seems to be located exclusively on the non-cytoplasmic surface[18,80] and several functions have been proposed to take this restricted location into account.

At one level, carbohydrate is regarded as important for membrane biosynthesis[20]. It is likely that in nucleated cells all membrane proteins are initially incorporated into the rough endoplasmic reticulum. From there, they diffuse, or are conveyed, to their different membrane locations within the cell—the smooth endoplasmic reticulum, nuclear membrane, Golgi apparatus or plasma membrane. But the detailed mechanism for how these proteins are initially placed in the rough endoplasmic reticulum is unknown; it is often supposed that this is done during synthesis by secretory ribosomes bound to the endoplasmic reticulum, implying that membrane proteins are a special class of secreted protein. The alternative view[20] is that membrane proteins are initially synthesised as soluble proteins which dissolve into the endoplasmic reticulum from the cytoplasm. To "lock" these proteins into the membrane, they are glycosylated from the lumen side of the endoplasmic reticulum by a large number of different glycosyl transferases, which are specific for the sugar, acceptor site and the linkage catalysed. This scheme places the onus of anchoring those proteins (which span the membrane) on the carbohydrate. Without this "lock", the protein could diffuse back into the cytoplasm, a situation which would make it much more difficult for a cell to maintain specific proteins in specific membranes. In bacteria, in which only one membrane (the plasma membrane) exists, no such problem arises and membrane proteins are generally not glycosylated. Once in the rough endoplasmic reticulum, proteins destined for the plasma membrane move to the Golgi complex where more extensive glycosylation occurs; finally, they pinch off the Golgi apparatus in vesicles which fuse with the plasma membrane[81].

But the idea that carbohydrate acts as a "lock" on those proteins which span the membrane does not explain the observed complexity of carbohydrate sequences A simple oligosaccharide (such as penta-sialic acid) would do as a "lock", without any need for the wide variety of oligosaccharide chains which exist. One is therefore inclined to look further for additional functions. The potential of complex oligosaccharide labels for the purpose of specific cell–cell recognition has not escaped notice[82], and it seems possible that they could have such a role The indirect nature of the genetic control, however, and the resulting variability in the extent of glycosylation, could allow a worrying amount of degeneracy if such a system were used for fine specificity in cell marking. Nevertheless, the consistent differences in oligosaccharide side chains between and among the different glycolipids and glycoproteins indicate the existence of important mechanisms for controlling their glycosylation.

The terms "cell coat" or "glycocalyx" refer to the carbohydrate-rich peripheral zone found at the surface of all mammalian cells, which can be visualised by a variety of stains more or less specific for carbohydrate, such as ruthenium red[83]. The carbohydrate consists of the oligosaccharide side chains of plasma membrane glycolipids and glycoproteins, including in some cases, adsorbed glycoproteins and mucopolysaccharides (proteoglycans). This high concentration of cell surface carbohydrate must have an important influence on many of the functions of the plasma membrane, but the nature of these influences is poorly understood. The use of highly purified glycosidases and mutant cell clones deficient in certain cell surface monosaccharides[84] should prove useful in this respect

Conclusions

All biological membranes, including mammalian plasma membranes, are structurally based on a lipid bilayer. The strongest evidence for this comes from the susceptibility of the membranes to fracture across their mid-planes at low temperature. The bilayer can be visualised as a two-dimensional fluid, with the individual lipid molecules asymmetrically distributed between the two leaflets and able to diffuse in the plane of their own monolayer. Into this lipid matrix, which provides the basic structure of the membrane, specific proteins are inserted asymmetrically and these are responsible for most of the membrane's functional properties. In the case of the plasma membrane, these functions include the receiving and transducing of various extracellular chemical signals (such as hormones, growth factors, neurotransmitters, antigens), cell junction formation (gap, tight, and synaptic), transport of small molecules, endocytosis (pinocytosis and phagocytosis) and exocytosis. Some of the membrane proteins span the bilayer, either as a simply coiled hydrophobic segment (as in the erythrocyte MN glycoprotein) or in a more folded globular state. Most, if not all, of these are glycosylated, having all of the carbohydrate on the non-cytoplasmic side, which probably serves to lock the proteins in place. Since there is no evidence in the erythrocyte (or any other) plasma membrane for a protein which is inserted solely into the outer monolayer of the membrane, it is likely that every membrane glycoprotein spans the bilayer. It seems probable that most of the polypeptides exposed on the cell surface which do not span the membrane (for example, β_2-microglobulin) are held in place by association with other polypeptides which do so.

In human erythrocytes, the major glycoproteins which span the membrane probably comprise the majority of the intramembrane particles seen in the fracture plane; they do not turn over (if lost, they could not be replaced) and their in-plane mobility is markedly restricted, probably because they are tethered from within by spectrin. In contrast, in nucleated cells, most of the readily detectable surface-exposed plasma membrane proteins seem not to be associated with intramembrane particles, are rapidly turning over and are mobile in the membrane plane; on the other hand, membrane proteins interacting between nucleated cells at sites of specialised intercellular junctions often appear to be associated with particles, are restricted in translational mobility, and turn over comparatively slowly. Little is known about the in-plane mobility or turnover of non-junctional proteins seen as particles. In addition, there is evidence that the cytoplasmic fibrous proteins of nucleated cells, such as microfilaments and microtubules, can control the distribution and translational movement of some membrane proteins.

There are obvious advantages in having a fluid membrane in which molecules can diffuse freely. It may enable membrane enzymes and their lipophilic substrates to come together and interact, and it provides a simple means of distributing proteins and lipids to regions of the membrane remote from where they are inserted, and for dividing membrane components evenly between daughter cells at the time of cell division. In addition, it would be expected to facilitate cell locomotion and membrane fusion, and allow a more adaptable fit between receptors and multivalent ligands or other cells. The alternative of having a frozen and thus rigid lipid bilayer could be dangerous to the cell, as a slight deformation might crack the membrane and lead to the loss of cytoplasmic components On the other hand, in some circumstances (such as during locomotion), a mechanism for controlling the distribution and mobility of membrane proteins within the fluid milieu is essential. This balance between freedom and control is seen in all things, not least of which is the mammalian plasma membrane.

We thank Drs B. Gomperts and R. D. Kornberg for helpful discussions, and Drs F. Frankel, B. Gomperts, C. Hughes, R. D. Kornberg and A. Raff for commenting on a first draft of the manuscript. The bibliography is incomplete and meant only as a way into the relevant literature; it often refers to reviews and recent examples at the expense of original observations.

Mapping of the G_1 phase of a mammalian cell cycle

P. M. Naha, A. L. Meyer & Kathleen Hewitt

Paterson Laboratories, Christie Hospital and Holt Radium Institute, Manchester M20 9BX, UK

Temperature-sensitive variant clones of BALB/3T3 cells were put on a linear time scale map by measuring their time of entry into S phase; these clones seemed to accumulate a unique non-histone protein at the restricted temperature.

THERE is an extensive literature on the biochemistry and control mechanisms of the four phases of the cell cycle[1] (for reviews see refs 2 and 3); but little is known of the biochemical events in G_1 (between completion of mitosis and onset of DNA synthesis) and G_2 (between completion of DNA synthesis and mitosis). The production of RNA and proteins involved in the initiation, progress and termination of DNA synthesis are some of the main events attributed to G_1 and G_2 (refs 2 and 3); however, most of the evidence was indirect since selective inhibitory agents (for example, dactinomycin) were used. Other investigators[4] have referred to the resting (in respect of proliferation) cells as being in G_0, distinct from G_1, which can be stimulated to divide by an appropriate stimulus[5]. Such non-growth states can be achieved experimentally and attention has focused recently on cells so arrested in G$_1$ as potential "target cells" for carcinogenic transformation[6,7]. It has also been suggested that there are some rate controlling signals in G$_1$ itself and at the G$_1$/S boundary which have regulatory functions[8–10]. We have mapped G$_1$ of a mammalian cell cycle using temperature-sensitive variant cell lines. There have been several reports of variant clones defective in G$_1$ (refs 11–15), but for a comprehensive study a linear time scale map is essential, and this article presents data on such a map.

An aneuploid clone (A31) of BALB/3T3 (ref. 16) was obtained from Imperial Cancer Research Fund Laboratories, London. The culture was maintained in L-15 medium[17] with 10% foetal bovine serum (FBS), penicillin (100 U ml^{-1}) and streptomycin (50 µg ml^{-1}) at 33 °C. Temperature-sensitive variant clones were maintained in similar conditions. A preliminary study of the generation time of wild-type BALB/3T3 cells showed that between 33 °C and 38 °C the cells doubled at approximately the same rate (21±0.5 h and 20±0.75 h, respectively). Replicate cell cultures plated at 1,000 per Falcon tissue culture plates (60× 15 mm) at 38 °C were exposed to doses of N-methyl-N′-nitrosoguanidine (MNNG) (Aldrich, 05 µg ml^{-1}) every 90 min for 9 h after plating. This was done to catch cells at different stages of G$_1$ in an asynchronous population. After 2 h of treatment with MNNG (lethality less than 50%) cells were exposed to either 2.5×10^{-4} M 5-bromo-2-deoxyuridine (BUdR, Sigma)[18] or 6-^{3}H-thymidine[19] (5 µCi ml^{-1}, 32 Ci mmol^{-1}) for 2 h in a prewarmed medium at 38 °C to kill the DNA-synthesising cells selectively. The culture plates were then washed in normal growth medium (L-15) with 10% FBS and incubated at 33 °C until discrete clones were visible. Half the medium was replaced every 3 d Isolated clones were purified further from single cell colonies through two successive reclonings. Forty-five temperature-sensitive clones were isolated after preliminary selection in this way. Of these, eight were studied because they were relatively the least 'leaky'—A8, A69, A83, A90, A92, A122, A123 and B23.

Table 1 Colony-forming ability of BALB/3T3 and temperature-sensitive variants at 33 °C and 38 °C after 7–10 d of incubation

Clones	No. of input cells per 25 cm^2 Falcon tissue culture flasks							
	5×10^2 cells		1×10^3 cells		5×10^3 cells		1×10^4 cells	
	33 °C	38 °C	33 °C	38 °C	33 °C	38 °C	33 °C	38 °C
Wild type	56±3	61±7	82±7	116±4	c	c	c	c
A8	29±3.3	0	71±5	0	c	26±8	c	73±11

B23	18±4.6	0	40±5.5	0	c	106±10	c	c

To determine colony-forming ability, trypsinised cells were plated in 25 cm^2 Falcon tissue culture flasks at a density of 10,000, 5,000, 1,000 and 500 per flask in L-15 medium Replicate cultures were incubated at 33 °C and 38 °C for 7–10 d. Half the medium was replaced every 3 d. Finally, the cultures were stained in Giemsa. c, Confluent culture (> 250 colonies).

These variant clones differed (4–12%) in their ability to form colonies at 33 °C when plated at 1,000 and 500 cells per flask, but almost no colony grew in any of them at 38 °C at these densities (Table 1). Compared with the variant cells, the parental cell line had more colonies growing at 38 °C (11.6%) than at 33 °C (8 2%). At greater densities (5,000 and above) variant clones would grow and appeared more and more leaky at the restricted temperature (38 °C). Temperature shift-down after 10 h at 38 °C revealed no significant decrease in colony formation in any temperature-sensitive variant. This suggested that the temperature-sensitive defects were at least partly reversible, but were irreversibly impaired during prolonged incubation at 38 °C. To pinpoint the phase of the cell cycle when the temperature-sensitive cells were defective we compared the cell cycles of wild-type BALB/3T3 and temperature-sensitive variants at 33 °C and 38 °C. In general we followed Baserga's[20] method. We counted labelled cells in mitosis in 200 metaphase plates of each sample. The labelled metaphases represented cells that had gone through G$_2$, mitosis, G$_1$, S, second G$_2$ and mitosis after a pulse label. The average generation time was estimated from the difference between 50% points on the two ascending limbs of the biphasic curve[20,21]. Mitotic index was calculated from the same preparations by counting the average number of cells in mitosis in 50 microscopic fields. The data for two temperature-sensitive clones are presented here for comparison with the parental cell line. The division cycle of cells showed (Fig. 1*a*–*c*) that the duration of one cell cycle in wild-type BALB/3T3 (Fig. 1*a*) was approximately 20.5 h at both 33 °C and 38 °C, but the distribution of the four phases differed slightly At 38 °C, the durations of phases were G$_1$+M, 6 5 h; S, 10.5 h, and G$_2$, 3.5 h, whereas at 33 °C they were G$_1$+M, 8.5 h; S, 9.5 h; and G$_2$, 2.5 h. In the variant clones A8 (Fig. 1*b*) and A83 (Fig. 1*c*), however, S seemed to be slightly longer at 33 °C, but at 38 °C both clones failed to reach S. Labelled cells in mitosis did not exceed 50% in the variant clones at 38 °C. This was true for all eight variant clones.

Mitotic indices counted from the same preparations showed (Fig. 1*a*–*c*) that at 33 °C the variant clones A8 and A83, behaved very similarly to the parental cell line, the mitotic index increasing from 1–2% to about 4.8%. At 38 °C, however, mitotic indices were significantly different. The parental culture and clone A8 had mitotic indices more or less indentical to those at 33 °C; in clone A83, on the other hand, the mitotic index rose from 1.6% to 48.8% between 12 and 24 h at 38 °C. The latter was at first thought to indicate cells arrested in mitosis, similar to the situation with colchicine treatment, but an analysis of the cells at different stages of mitosis (prophase : metaphase : anaphase : telophase) was more or less similar between 12 and 24 h (1.6: 5.6: 1.0: 1.5 respectively). If anything there was an accumulation of cells in anaphase and telophase during the later stages of incubation of A83 at 38 °C. This may represent a slowing down of 'transit' through all phases of mitosis. We checked this by testing the viability of the cells arrested at 38 °C by means of temperature shift-down (from 38 °C to 33 °C). We found that the longer the cultures were incubated at 38 °C, the larger the number of cells entering S phase, though they were delayed This indicated that many A83 cells arrested at 38 °C remained viable for the next 10–12 h. The variants were mapped by timing the start of DNA synthesis For this purpose, 1×10^5 cells per ml were seeded in Leighton tubes on coverslips in 1 ml volumes as before The culture tubes were incubated for one generation time (20 h) at 33 °C; thereafter the cultures were transferred to 38 °C except for one set of controls. Replicate culture tubes (in triplicate) were incubated at 38 °C for 2, 4, 6, 8 and 10 h and transferred back to 33 °C for 8, 6, 4, 2 and 0 h, respectively. From the 10th hour, culture tubes from each set of transfers were pulse labelled for 10 min with 6-^{3}H-thymidine (5 μCi ml^{-1}, 32 mCi mmol^{-1}) at 33 °C every hour for 12 h. Preliminary studies of the cell cycle of the parental line (Fig. 1) showed that the cells

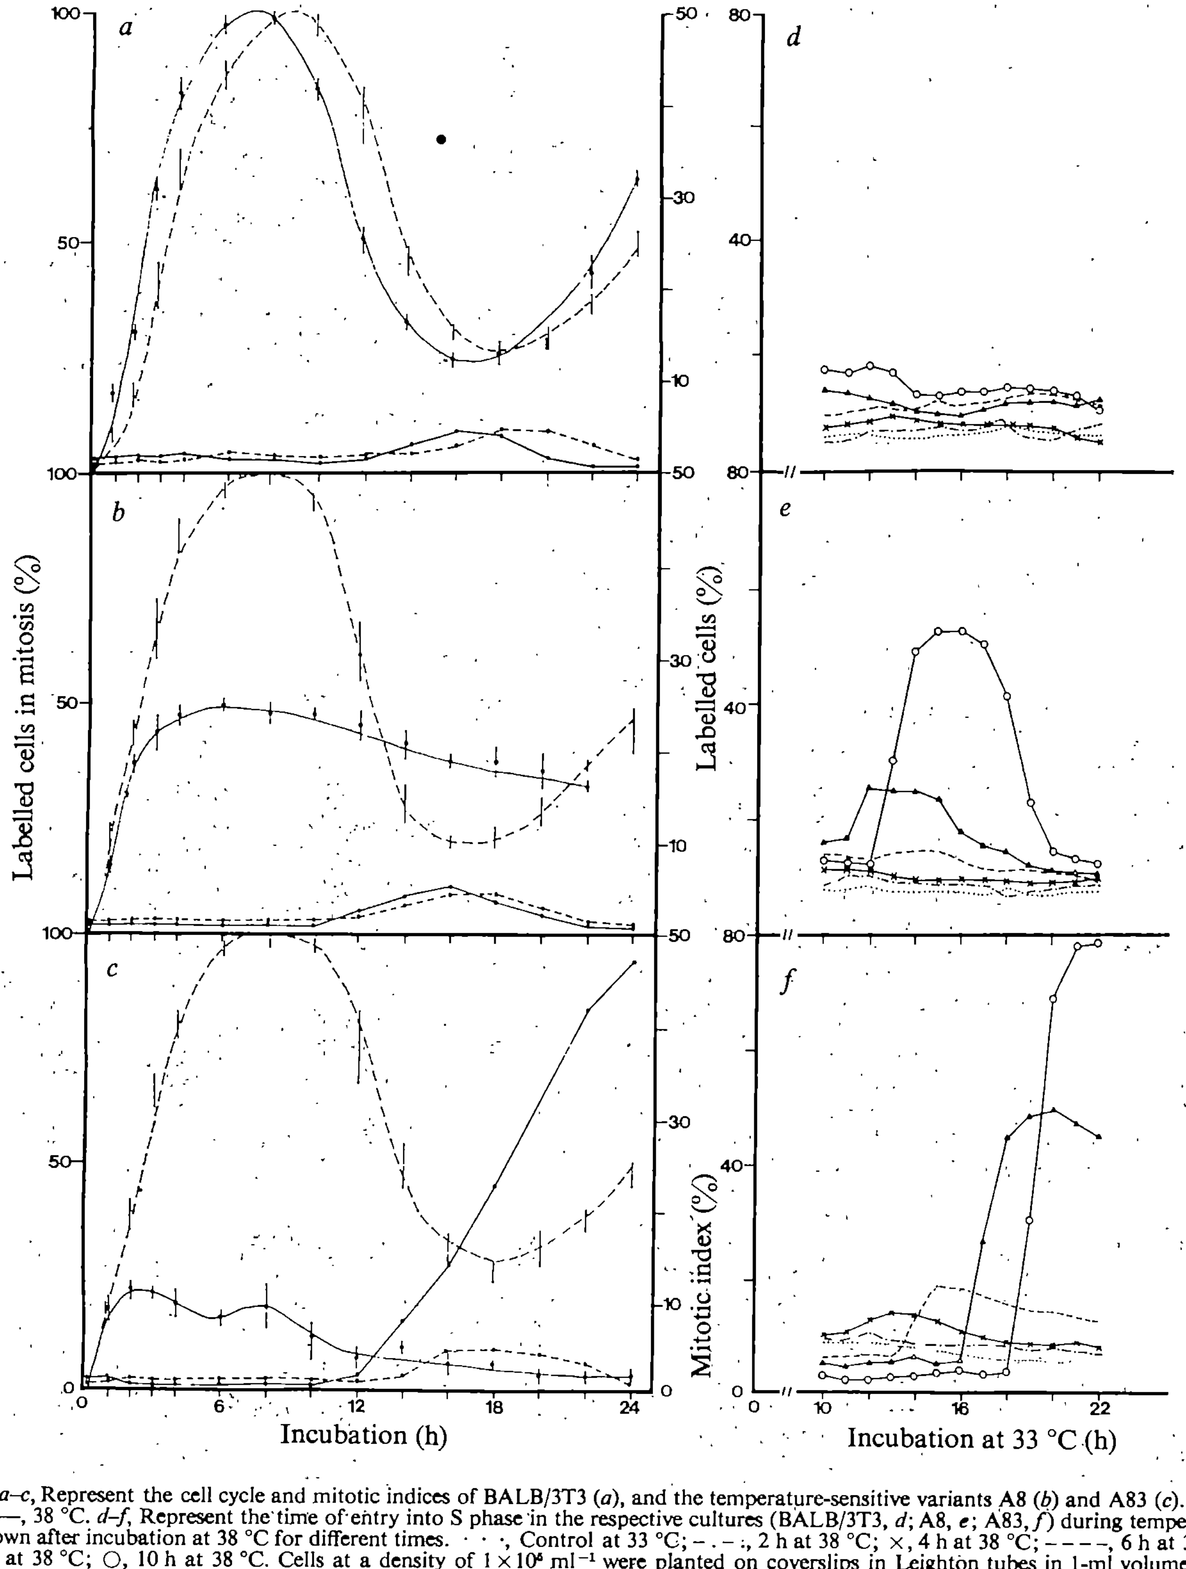

Fig. 1 *a–c*, Represent the cell cycle and mitotic indices of BALB/3T3 (*a*), and the temperature-sensitive variants A8 (*b*) and A83 (*c*). – – –, 33 °C; —, 38 °C. *d–f*, Represent the time of entry into S phase in the respective cultures (BALB/3T3, *d*; A8, *e*; A83, *f*) during temperature shift-down after incubation at 38 °C for different times. · · ·, Control at 33 °C; – . – ., 2 h at 38 °C; ×, 4 h at 38 °C; – – – –, 6 h at 38 °C; △, 8 h at 38 °C; ○, 10 h at 38 °C. Cells at a density of 1×10^5 ml^{-1} were planted on coverslips in Leighton tubes in 1-ml volumes and incubated for 36 h at 33 °C to enable the cells to reach the log phase of growth. Cells were then exposed to 6-^{3}H-thymidine at a concentration of 1 µCi ml^{-1} (5 Ci mmol^{-1}) for 10 min and washed in Hanks' balanced salt solution (BSS) containing cold thymidine (5 µg ml^{-1}) to dilute the remaining radioactivity in the cells. Finally, the cells were placed in L-15 medium containing cold thymidine (5 µg ml^{-1}); replicate tubes were incubated at 33 °C and 38 °C. At hourly or two-hourly intervals one set of tubes was fixed, autoradiographed and stained by the following method. After removing the medium, cells were treated with a hypotonic solution of Hanks' BSS in water (1:4) for 5 min, fixed for 5 min in acetic acid: ethanol (1:3) diluted in the hypotonic solution, and then fixed for a further 10 min in undiluted fixative. The coverslips were air dried and mounted in glass slides with the cells on the upper side. The slides were then dipped in Ilford L-4 liquid emulsion and exposed for 2 weeks in the dark at –20 °C. After 2 weeks the slides were developed in D19 developer, dried and stained in 4% buffered Giemsa.

entered S between 8.5 and 10 h. The design of our experiments was expected to enable the parental cell line to enter without delay; but a fractional population with a defect in G_1 in the variant cell line would be delayed in its biochemical processes and would thus enter S late. The time a variant culture was delayed in entering S was calculated to be the time (map distance) from the S phase with respect to the parental culture. This map of G_1 variants is strictly a measure of their time of entry into S; it is not a complementation or genetic map.

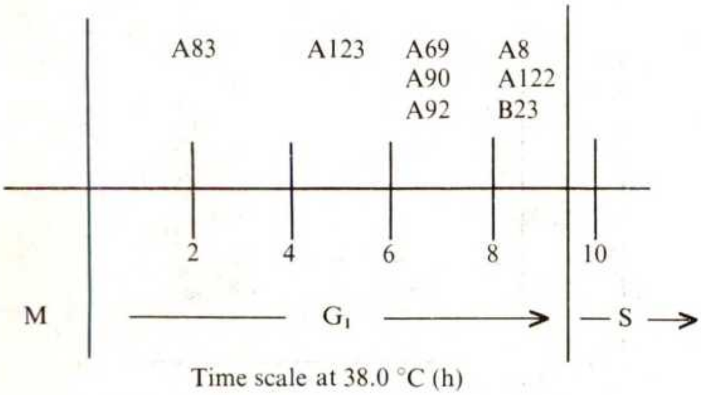

Fig. 2 Tentative map of the G_1 phase of the cell cycle of temperature-sensitive clones of BALB/3T3 cells, measured with respect to the time of the block and entry into S phase.

The coverslips from each tube after exposure to radioactivity were washed, fixed and autoradiographed as in the cell cycle experiment. The percentage of labelled cells was counted from 50 microscopic fields; cells in active DNA synthesis were counted for 12 h. The results showed (Fig. 1*d*–*f*) that in the wild type parental culture (Fig. 1*d*) there was no G_1 accumulation of cells entering S during successive transfers from 38 °C; if anything, the percentage of labelled cells was slightly higher in the last two transfers at 8 h (9.6%) and at 10 h (14.6%), indicating more cells already entering S at 38 °C. The number of labelled cells, however, decreased as the culture progressed through the growth cycle at 33 °C. The variant clones A8 (Fig. 1*e*) and A83 (Fig. 1*f*), on the other hand, had presumably accumulated cells in G_1 during longer periods of incubation at 38 °C so that the cells were delayed in entering S for different times; this was reflected in the larger number of labelled cells appearing in later transfers. In the variant clone A8, the delay in entering the S phase and consequent accumulation of labelled cells appeared between 8 and 10 h incubation at 38 °C, whereas in clone A83 the delay and accumulation of cells entering S were first observed between 2 and 4 h incubation at 38 °C. It is interesting to compare the corresponding increase in the percentage of labelled cells in the variant clones during longer periods of incubation at 38 °C. In clone A8, the number of labelled cells increased from 16.6% to 25.8% after 8 h of incubation at 38 °C (Fig. 1*e*); but after 10 h at 38 °C the number of labelled cells increased from 12.0% to 52.2%, though entry into S was delayed by 2 h in the latter case. The same appeared to be true for A83. After 4 h of incubation at 38 °C (Fig. 1*f*) cells started to accumulate in G_1, denoted by a corresponding delay in entering S at 33 °C. The percentage of labelled cells among those transferred after 8 h increased from 5.9% to 58.4%; after 10 h at 38 °C it increased from 3.8% to 78.4%. These results indicated that the variant cultures attained 'partial synchrony' in entering S phase because they had longer periods of incubation at the restricted temperature (38 °C); the cells were presumed to be arrested in G_1.

The 'partial synchrony' was soon lost after the cells were shifted to 33 °C. In both A8 and A83, 'synchronised' populations began to lose synchrony within 3–4 h at 33 °C; the percentage of labelled cells decreased sharply instead of forming a plateau. Since the measured time for S phase was between 10 and 12 h at 33 °C, the synchrony was probably lost halfway into the S phase in these variant cell lines.

The duration of the S phase in the parental and variant (A8, A83) cultures being about 10 h at 33 °C (half the generation time for each cell), at least 50% of cells would be expected to be labelled with ^{3}H-thymidine at any time in the control cultures, but we observed only 10–20% labelling of cells at 33 °C. This was thought to be due to either (1) lower efficiency of plating (<50%) in these cells, or (2) many cells not actively cycling in these early log phase cultures incubated for 20 h at 33 °C. This series of experiments was conducted for each of the other six variant clones. On the basis of their time of entry in S, the 'mutant' cells were tentatively put on a linear time scale map (Fig. 2). (The final assignment of these 'mutant' clones on a genetic map awaits completion of complementation tests now in progress.)

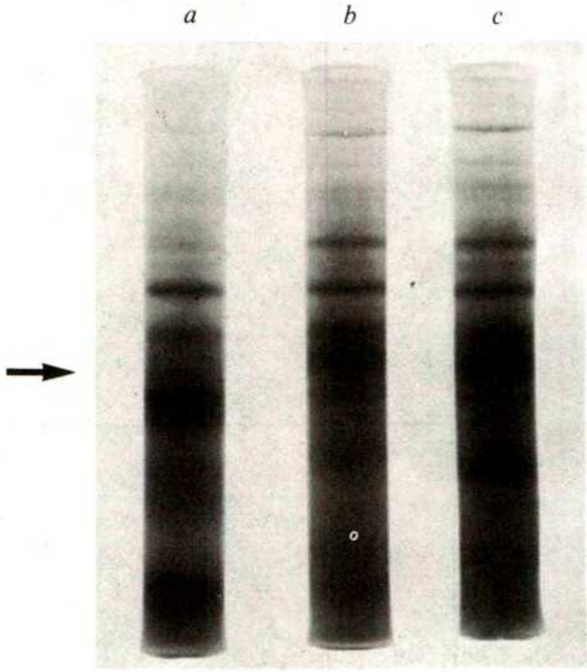

Fig. 3 Polyacrylamide gel electrophoresis of 100 µg of nuclear proteins of cultures, at 38 °C, of parental cell line of BALB/3T3 (*a*), clone A8 (*b*) and clone A83 (*c*). Cells at a density of 1×10^{-5} ml^{-1} in 30 ml volumes were plated in 16-ounce glass bottles and incubated for 16 h at 38 °C. Cultures were collected from the bottles after two washes with cold phosphate-buffered saline (PBS) in 1 ml of 1% Nonidet P40. Cells were then washed with PBS and frozen. Nuclear proteins were prepared by the methods described in Fig. 4. Gels were stained with 2% naphthalene black.

We analysed the nuclear proteins in the two variant clones (A8, A83) and the parental clone, grown for 16 h at the restricted temperature (38 °C) to identify possible biochemical alteration in the nuclei of the variants at the restricted temperature. Nuclear proteins were prepared as before[22]. Equal amounts (100 µg in 0.2 ml) were run on 6% acrylamide disc gels with sodium dodecyl sulphate in a continuous system[22]. Stained preparations of these gels revealed

(Fig. 3) a unique protein in both variant clones (Fig. 3). On the other hand, several low molecular weight proteins at the bottom of the gel in the parental type were absent from the variant clones. There was, however, similarity in the electrophoretic profiles of the nuclear proteins in the two variant clones which are widely separated in our time scale map of G_1.

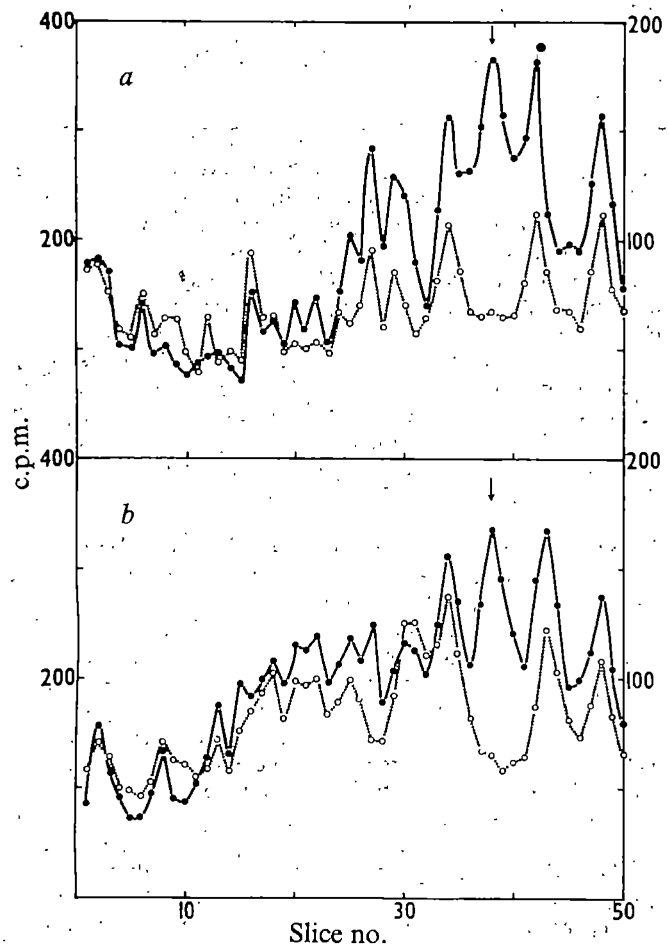

Fig. 4 *a*, Distribution of ^{3}H-tryptophan (●) and ^{14}C-methionine (○) in 100 μg of nuclear protein of clone A83. Cells were incubated for 16 h at 38 °C and double labelled with radioactive amino acids for 1 h at 38 °C. *b*, Distribution of ^{3}H-tryptophan (●) and ^{14}C-tryptophan (○) in coelectrophoresis of 100 μg of nuclear proteins of clone A83 grown at 38 °C and 33 °C respectively for 16 h and exposed to radioactive medium for 1 h at their respective temperatures. Quantitation of the nuclear proteins was performed as follows. Cells at a density of 1×10^5 ml^{-1} in 30 ml volumes were plated in 16-ounce glass bottles and incubated for 16 h at 38 °C. The cells were then washed with Hanks' BSS and exposed to Hanks' BSS with L-methionine-methyl-^{14}C (10 μg ml^{-1}, 56 mCi mmol^{-1}), or L-(methylene-^{14}C)-tryptophan (10 μg ml^{-1}, 2Ci mmol^{-1}), and L-tryptophan-^{3}H-G (24 μg ml^{-1}, 5 Ci mmol^{-1}) for 1 h at 38 °C. Cultures were collected from the bottles after two washes, with cold PBS, in 1 ml of 1% Nonidet P40. Cells were then washed with PBS and frozen. Frozen cell pellets were washed and resuspended in rabbit reticulocyte standard buffer (RSB, *p*H 7.4) and allowed to swell for 10 min at 2 °C. The cells were homogenised on a Dounce homogeniser, using 10–15 strokes. In these conditions, 95–100% of cells released intact nuclei and cytoplasm. Nuclei were centrifuged at 500*g* for 15 min and washed with RSB. The nuclear pellets were resuspended in RSB (10^7 nuclei ml^{-1}) and disrupted by sonication for 5 min at full power in a Soniprobe Type 7530A sonic oscillator. The nuclear fraction (100 μg in 0.2 ml) was first reduced by treating it with 0.5 ml of a mixture of 10 M urea, 4% SDS and 4% mercaptoethanol and heating at 100 °C for 3–5 min. The sample was run on 6% acrylamide gels with SDS in a continuous system. The distribution of radioactive proteins in the gels was determined by slicing the gel into 1-mm thick sections, dissolving it in 0.5 ml of H_2O_2 at 60 °C and counting in toluene scintillation fluid (toluene–Triton, 1:1).

For a qualitative and quantitative estimation of the different proteins in the gels, the variant A83 cells were labelled and the radioactivity in the nuclear proteins was analysed. The distributions of radioactive proteins, doubly labelled at the restricted temperature with ^{14}C-methionine and ^{3}H-tryptophan showed (Fig. 4*a*) a high rate of incorporation of tryptophan in the band indicated. Since tryptophan is incorporated selectively into non-histone proteins, we presume that this fraction is a non-histone protein. To acquire further evidence that this protein accumulated only at the restricted temperature equal amounts of nuclear proteins (100 μg) of ^{3}H-tryptophan-labelled A83 cells at 38 °C and ^{14}C-tryptophan-labelled A83 cells at 33 °C were run together; they did not band in the same molecular weight region (Fig. 4*b*). Appearance of an identical non-histone protein in the two variant clones, A8 and A83, defective in G_1 suggests that these variant clones were accumulating a protein that was not involved in turnover at 38 °C. Isolation and characterisation of this protein has now been undertaken.

Our results show that temperature-sensitive cell lines could provide a useful tool for study of the control of the cell cycle in mammalian cell systems, particularly in the identification of endogenous components necessary for the regulation of cell growth. There are increasing indications that differentiation and carcinogenesis are related to regulatory changes in a cell[23,24] which are possibly determined during G_1. A tendency for different mammalian cell types to have G_2 and M of similar durations but a G_1 of widely varying durations has been offered repeatedly as evidence that controlling events occur in G_1 (refs 20, 25 and 26). A significant conclusion from our experiments is that some of the events controlled in G_1 are apparently sequential with respect to their biochemical events. Arresting any of these events delayed the subsequent processes.

The molecular mechanism involved in the alterations of a particular enzymatic function in the temperature-sensitive cells is not well understood. Whether the variant clones in a conditionally defective state (at the restricted temperaure) make an altered enzymatically inactive protein ("missense") or no protein at all ("nonsense") has yet to be resolved. To what extent these structurally altered proteins could be corrected, and the time it would take for the correct resolution might to a certain extent jeopardise a linear time scale map over short sequences, but over long sequences such a map would probably provide a good foundation for the study of functions controlled in G_1.

Nuclease that preferentially inactivates DNA containing mismatched bases

Heteroduplex and homoduplex DNA molecules of bacteriophage SPP1 were treated with DNase I, an enzyme of Ustilago maydis *implicated in genetic recombination. A transfection assay with* Bacillus subtilis *demonstrates that the heteroduplexes are preferentially inactivated.*

It is widely accepted that hybrid or heteroduplex DNA is an essential intermediate in genetic recombination[1-5]. In heterozygous crosses, the inclusion of a genetic marker within a hybrid DNA segment will result in the formation of a mismatched base pair. It was suggested that gene conversion (non-reciprocal allelic recombination) could be due to the repair of such mismatched bases[6,7]. Genetic evidence for such repair with artificially made heteroduplexes has subsequently been obtained in transfection experiments with bacteriophage SPP1 of *B. subtilis*[8], in phage λ[9,10], as well as in transformation with *Pneumococcus*[11] and studies on gene conversion and post-meiotic segregation in *Ascobolus*[12]. An initial step in the repair of mismatched bases is presumed to involve an enzyme that cleaves one strand of the DNA at or near the mismatched region, analogous to the initial step in pyrimidine dimer excision repair.

A search for such an enzyme in the fungus *Ustilago maydis* was initiated by the isolation of DNase deficient mutants, which were also defective in the process of gene conversion[13,14]. The deficiency of gene conversion was shown to be associated with a low level of a nuclease, DNase I[15]. We show here that this enzyme preferentially inactivates heteroduplex molecules containing a single mismatched base pair or a deletion, as well as molecules containing pyrimidine dimers.

Ustilago nuclease and SPP1 transfection

The enzyme has been purified 8,600-fold from wild-type extracts and has been fully characterised[14-16]. Like the related nucleases of *Neurospora crassa*[17] and *Aspergillus nidulans*[18], it is most active on single-stranded DNA substrates. Although it does not degrade native DNA to acid soluble products, alkaline sucrose gradient analysis showed that single-strand nicks are introduced in such molecules. Previous irradiation of the substrate with ultraviolet light increases the number of nicks introduced, which indicates that the enzyme recognises minor distortions in DNA. This activity on native DNA is not due to a second contaminating nuclease. The enzyme is unusual in having no activity on circular DNA, whether single or double stranded. Free ends of DNA molecules are therefore essential for its activity.

Native DNA from phage SPP1 is taken up by competent cells of *B. subtilis*, which later produce a burst of phage particles[19]. The strands of SPP1 DNA after complexing with RNA can readily be separated in CsCl density gradients. Separated complementary strands obtained from mutant and wild-type phages can be reannealed to form biologically active homoduplex and heteroduplex molecules[8,20]. It is known (personal communication from H. C. Spatz and T. A. Trautner), that a single-strand nick inactivates the molecule in the transfection assay. The availability of defined homoduplex and heteroduplex molecules provides a very sensitive substrate for any enzyme which specifically attacks heteroduplex molecules.

Hydroxylamine-induced (G–C→A–T) plaque-type mutants have been isolated in SPP1 phage. Most of the experiments involve one of these, mutant 161. The mismatches in heteroduplex DNA therefore involve single bases, the pairs being either adenine–cytosine or guanine–thymine. Many deletion mutants have been isolated. We have used one, 4307, which lacks up to 3% of the genome, as judged by its buoyant density and its sensitivity to citrate inactivation (personal communication from G. Klotz and T. A. Trautner).

Inactivation of hetero- and homoduplex DNA

The two heteroduplexes, two homoduplexes and native DNA were exposed to *Ustilago* nuclease for 15 min under standard assay conditions (see legend to Table 1). Competent cells were added and incubated for 30 min at 37 °C. The cells were then diluted and plated to score the number of infective centres.

The difference between the inactivation of homoduplex and heteroduplex substrates was about sixfold in the experiment in Table 1; in all experiments it varied between three- and sevenfold. Nevertheless, significant inactivation of native and homoduplex was seen, which could be due to contaminating nuclease activity. This possibility, however, seems very unlikely on the basis of results from experiments done to dissociate the nonspecific activity (on homoduplex or native DNA) from the specific activity (on heteroduplex DNA). In experiments in which the salt concentration of the reaction mixture was varied, or different dilutions of the enzyme were used, reduction or loss in specific activity led to a simultaneous reduction or loss of the nonspecific activity. It therefore seems probable that a proportion of the native and homoduplex molecules are imperfect structures. The process of hybridisation may increase the proportion of defective molecules and therefore tend to minimise the difference between homoduplex and heteroduplex

Table 1 Inactivation of native, homoduplex and heteroduplex DNA by DNase I

Type of DNA		Infective centres No enzyme	Infective centres + enzyme	% Surviving Biological activity
Native SPP1		2.4×10^5	1.2×10^5	47.6
161/161	homoduplex	1.6×10^4	4.0×10^3	24.5
+/+		2.7×10^4	7.2×10^3	26.6
161/+	heteroduplex	3.3×10^4	1.2×10^3	3.6
+/161		2.1×10^4	8.2×10^3	3.9

The *Ustilago* enzyme was purified according to the procedure of Holloman and Holliday[15], and fraction V was used in all experiments. A solution containing 7,000 U ml^{-1} was diluted 1/10 in 10 mM Tris (*p*H 7.5) and 5 μl was incubated with 0.1 ml DNA (5 μg ml^{-1}; saturating conditions in transfection) and 0.1 ml of 10 mM $MgCl_2$ for 15 min at 37 °C. The reaction was terminated by adding 0.2 ml competent cells (a dilution effect). After addition of competent cells the standard transfection procedure was followed[19]. Each number represents infective molecules per ml, individual values being obtained from a total plaque count of ~ 600–800.

Table 2 The effect of DNase I on deletion heteroduplex and homoduplex DNA

Type of DNA		Infective centres No enzyme	Infective centres + enzyme	% Surviving Biological activity
4307/4307		2.5×10^3	1.7×10^3	70.3
+/4307	deletion hets	1.8×10^4	2.1×10^3	11.3
4307/+		6.5×10^3	1.2×10^3	18.9
+/161	point mutant hets	4.6×10^4	2.2×10^4	48.0
161/+		3.2×10^3	1.7×10^3	53.6

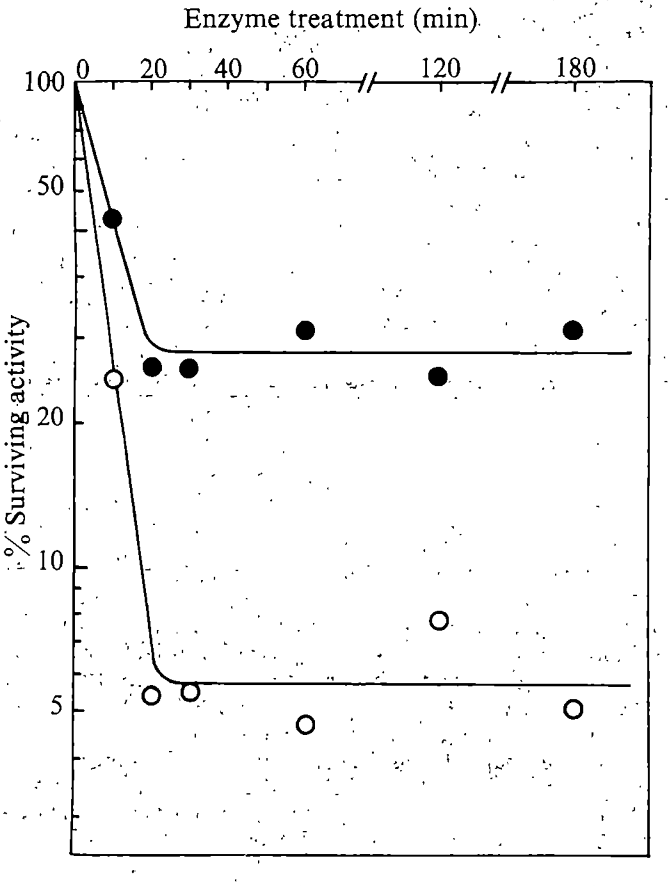
All types of DNA incubated for 15 min at 37 °C with 1/20 dilution of enzyme solution.

inactivation. Heteroduplexes containing the deletion 4307 are inactivated extremely rapidly in comparison with those containing a single base-pair mismatch (Table 2), suggesting a correlation between the distortion in the DNA and enzyme inactivation.

The kinetics of nuclease activity on homoduplex and heteroduplex DNA were followed by mixing DNA and enzyme at zero time. At appropriate intervals thereafter, samples were removed, transferred to tubes containing competent cells and incubated for 30 min at 37 °C to allow for maximum DNA uptake. The results of one such experiment are given in Fig. 1. The initial rate of heteroduplex inactivation was more rapid than with the homoduplex, but both types of DNA reached maximum, but different, inactivation levels after 15–20 min with DNase I. A proportion of the DNA molecules, yielding about 30 % infective centres (homoduplex) and about 5 % infective centres (heteroduplex), seemed to become resistant to the nuclease (see also Table 1).

The plateau in Fig. 1 could be due to a loss of enzyme activity after 15 min incubation or to a fraction of DNA molecules which is resistant to inactivation by the enzyme. The first alternative was excluded by adding fresh enzyme to three types of DNA that had already been incubated with the enzyme for 15 min. No further decrease in biological activity was observed (Fig. 2*a*). The second alternative was supported by the following experiment. We first incubated homoduplex DNA (161/161) and *Ustilago* DNase for 25 min, then added wild-type native SPP1 DNA and subsequently followed the kinetics of inactivation of both 161 DNA and wild type DNA. In SPP1 the wild type plaques, which form a halo, are easily distinguishable from the 161 plaques, which are haloless. This enabled us to follow the kinetics of inactivation of both mutant and wild type DNA simultaneously. Figure 2*b* shows that active nuclease molecules were present in the enzyme–DNA mixture that could not degrade the initial substrate any further, but efficiently attacked any new substrate that was presented.

Fig. 1 Kinetics of enzyme inactivation of homoduplex (●) and heteroduplex (○) DNA.



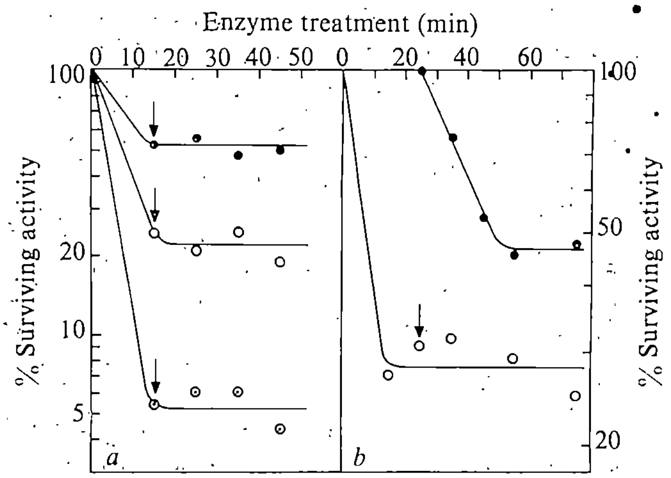


Fig. 2 *a*, Inactivation of native (●), homoduplex (○) and heteroduplex (○) DNA. The arrows indicate time of addition of further enzyme (5 µl 1/10 dilution). *b*, Initial inactivation of homoduplex (○) DNA, followed by inactivation of native DNA (●) added after 25 min.

As we have mentioned, DNase I requires free ends of DNA for activity[16]. It is possible that after binding to an end the enzyme diffuses along the DNA, introducing nicks at points where normal Watson–Crick base pairing is disturbed. We suggest that the preparation of DNase I we used contained a small fraction of defective or partially denatured molecules which bind to the ends of double-stranded DNA, but remain attached there. These would then prevent normal enzyme gaining access to the internal regions of the DNA. If our interpretation is correct, then the difference in the resistant fraction of native (~ 50 %) and heteroduplex DNA (~ 5 %) implies that normal enzyme molecules often monitor the former without introducing a nick. Alternatively, a population of DNA molecules which all contain a single-strand nick could have a residual biological activity of ~5 %. We do not yet have enough data to distinguish between the two possibilities.

We have previously compared the relative sensitivity of irradiated and unirradiated native T7 DNA to the *Ustilago* nuclease. Alkaline sucrose sedimentation patterns show that the enzyme prefers a substrate containing dimers[14]. In the SPP1 transfection system one can irradiate either heavy or light strands before hybridisation (the H strand has 20 % more pyrimidines than the L strand). As Fig. 3 shows, such hybrids when incubated with DNase I show a greater loss of biological activity than the untreated hybrids. In addition, we see a greater degree of inactivation when the irradiated strand is heavy.

Specificity and biological role of the enzyme

It has been shown that a nuclease isolated from *Neurospora* recognises and degrades single-stranded regions in deletion–wild type heteroduplexes[21]. Recently a similar nuclease (S1), isolated from *Aspergillus*[18], was also shown to be specific for

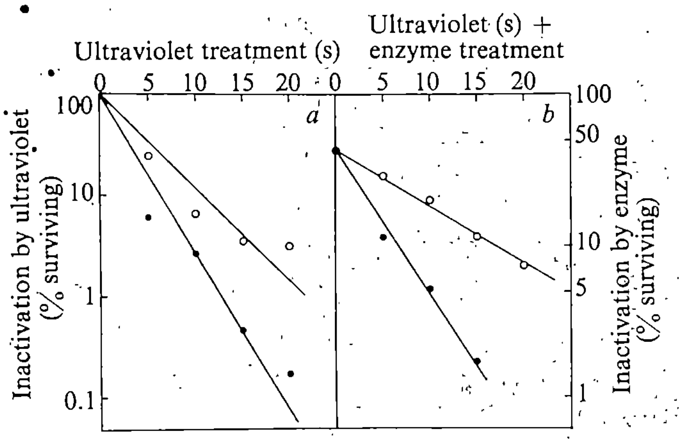

Fig. 3 Inactivation of DNA by ultraviolet light followed by DNase treatment. Single strands, either heavy (●) or light (○), were exposed to ultraviolet light (Sterisol, Hanau lamp, emitting 1.1 J m^{-2} s^{-1} at 30 cm). After hybridisation, DNA was treated for 15 min with DNase (as described in Table 1). *a*, Inactivation by ultraviolet without enzyme treatment; *b*, additional inactivation of the same substrates by a constant enzyme treatment.

mismatch-containing substrates[22]. The involvement of these enzymes in genetic processes is unknown because of the lack of mutants deficient in the enzymes. In the case of *U. maydis*, however, there is clear evidence that mutant strains which have a reduced amount of the enzyme in crude extracts have a barely detectable level of gene conversion[13,14].

The results we have obtained demonstrate that DNA containing a single purine–pyrimidine mismatch, which presumably produces a very minor distortion in DNA, is a preferred substrate to an identical one without the mismatch. A deletion–wild type heteroduplex is even more sensitive to the enzyme, possibly due to a greater distortion in the DNA. It is perhaps significant that addition or deletion mutants of *Ascobolus immersus* show gene conversion much more frequently than do base substitution mutants[12]. With the latter, postmeiotic segregation often occurs, suggesting that the correction enzyme is not very efficient at recognising these minor distortions in hybrid DNA.

The discovery of an enzyme which can recognise DNA containing a single mismatch provides strong evidence for the hypothesis that gene conversion is due to the correction of mismatched bases in heteroduplex DNA *in vivo*. As in ultraviolet repair by excision of pyrimidine dimers, it is likely that the overall correction process involves a mismatch-provoked degradation and resynthesis of a short region of single-stranded DNA[1,23,24]. DNase I may be involved only in the first step of this process. In the absence of information concerning the chemical nature of the degradation products of the enzyme, we cannot say anything about the actual event which leads to biological inactivation in our system.

The knowledge that enzymes exist which are specifically involved in mismatch repair leads one to consider the biological function or significance of such a correction mechanism. It is believed that incorrect bases may be removed at the replication fork by the editing function of DNA polymerases[25]. If this editing fails, however, and an incorrect base is inserted into DNA, correction enzymes such as DNase I could come into operation. Random repair provides no biological advantage over the segregation of mutant and wild-type strands after replication. One would therefore need to assume non-random repair leading to the excision of the newly synthesised 'wrong' strand. This could conceivably happen at the replication fork, where discontinuous synthesis would provide the necessary ends required for nuclease activity. If these nucleases are involved in general repair, it would be expected that mutants lacking such repair would have a mutator phenotype. Evidence suggests that *Pneumococcus* strains lacking the capability for heteroduplex repair have an abnormally high rate of spontaneous mutation[26]. An alternative or additional function of a correction enzyme could be the recognition and removal of damaged or abnormal bases in DNA, such as uracil, derived from the spontaneous deamination of cytosine[27]. Enzymes which recognise base pairs such as uracil–guanine may also detect other abnormal base-pair combinations.

We thank Miss Brigitte Diering for technical assistance. We also thank Thomas A. Trautner for useful criticisms and suggestions in preparing the manuscript.

letters to nature

New non-stellar BL Lacertae objects OY091 and PKS2335+03

DURING the past year, opinions on the nature of the BL Lacertae objects have narrowed to the association of elliptical galaxies with non-thermal sources which display continuous optical spectra. The study of the objects B2 1101+38 (Markarian 421) and B2 1652+39 (Markarian 501) indicates that they could be members of a sequence of elliptical galaxies ordered by the relative brightness of the BL Lac objects located in their nuclei[1]. On the other hand, the proximity of B2 1215+30, ON231, PKS1205−008 and PKS0048−097 to galaxies or nebulosities, has prompted the suggestion that, at least these four BL Lac objects have been ejected from the nuclei of their companion galaxies (J. J. Condon and D. L. Jauncey, unpublished). Furthermore, an analysis of the optical energy distribution[2] of

Table 1 Details of exposure

Exposure (min)	Filter	Emulsion
8	RG-2	103a-D
15	6,000–7,200Å (HBW)	103a-D
30	RG-2	IIIa-J

several BL Lac objects indicates that the decline of their optical spectra toward the ultraviolet becomes steeper because of the contribution of underlying elliptical galaxies. Typical examples are Markarian 501, AP Librae and BL Lac itself. In the case of AP Librae, the nebulosity was discovered with deep image tube photographs[3].

We undertook a search for nebulosities underlying the BL Lac objects 4C14.60, OT081, OY091 and PKS2335+03 and obtained positive results in the last two cases. These four objects appear stellar on glass copies of the National Geographic–Palomar Observatory Sky Survey. The selection of these objects was based on the steep decline of their spectra towards the ultraviolet[2]. Our observations were made with a 140-mm ITT image tube camera with a red-extended S-20 spectral response. The camera was used at the Cassegrain focus of the Steward Observatory 2.25-m telescope to obtain a 23′ field with a 10″ mm^{-1} scale. On the nights of August 2 and 3, 1975, we made three exposures of each of these four objects (see Table 1).

The objects 4C14.60 and OT081 remain stellar in appearance to the limit of our plates ($V \sim 22.5$ mag); however, both OY091 and PKS2335+03 exhibit non-stellar images on all of our plates. OY091, shown in Fig. 1, has a very soft image, with surrounding nebulosity highly reminiscent of that seen on deep plates of AP Librae[3]. Transmission scans in one dimension across the disk of OY091 clearly confirm the non-stellar image. The object PKS2335+03, shown in Fig. 2, is perhaps more interesting because the observed structure is clearly extended to the east, although there is also some fainter structure to the west. The distinct eastward extension resembles a jet or an extremely close companion.

The fields around OY091, PKS2335+03 and 4C14.60 contain many faint galaxies, suggesting a possible membership of these three objects with distant clusters of galaxies. In this respect OY091, PKS2335+03 and 4C14.60 are similar to PKS0548−322, which has been found to be projected on to a cluster of galaxies[4]. No evidence for a cluster of galaxies is observed on our plates of OT081; however, the low galactic latitude ($b^{II}=17.7°$) of this object, precludes a definitive statement. The association of BL Lac objects with clusters of galaxies is a matter which deserves further study.

Fig. 1 This reproduction of the field of OY091 is from a 30-min exposure with an RG-2 filter on a IIIa-J emulsion. North is at the top; east is to the left.

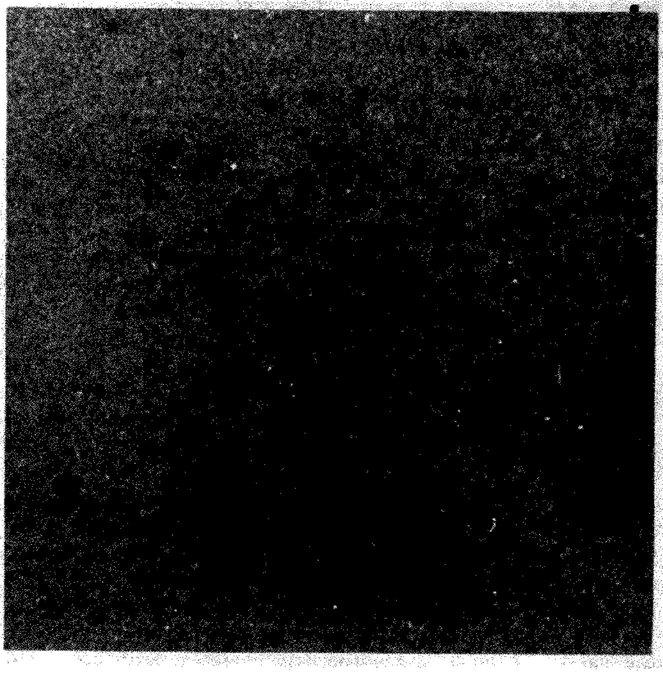

Fig. 2 PKS2335+03 is shown with the nebulous extension to the east in this reproduction of an 8-min exposure with an RG-2 filter on a 103a-D emulsion. Orientation as in Fig. 1.

The morphological classification of BL Lac objects suggests three possible groups: (1) objects located in galaxies, (2) objects associated with nearby galaxies and (3) isolated objects. Since the majority of the BL Lac objects seem to be somehow related to galaxies, it seems of interest to ask whether isolated BL Lac objects really exist, or will they eventually be found to be associated with galaxies? Because the ability to detect faint nebulosity, using photographic techniques, is a strong function of the distance to the object, it would be useful to find other observational parameters to detect associated galaxies. When a BL Lac object is located in a galaxy, the steepness of the optical energy distribution seems to be a useful parameter. The detection of underlying nebulosity in OY091 and PKS2335+03, two objects with spectral indices ($d \log F_\nu / d \log \nu$) of −2.7 and −2.3 respectively[2], tends to confirm this suggestion.

We thank R. Schiff of Steward Observatory for preparation of the photographic material. M. T. acknowledges support from an ESRO fellowship.

Cosmic rays and interstellar tunnels

MEASUREMENTS have been made[1] of the isotopic abundances of Be in cosmic rays, which have led to the conclusion that the typical cosmic ray lifetime in the galaxy is $\sim 2 \times 10^7$ yr. Furthermore, measurements[2] of the cosmic ray electron energy spectrum in the range 6–100 GeV, have shown a bend in the spectrum which can be attributed to inverse Compton and synchrotron losses. The position of the bend is indicative of the cosmic ray electron lifetime, and an age of 1.2×10^7 yr is derived.

These two values are significantly longer than the widely quoted value of $\sim 3 \times 10^6$ yr. This latter value is consistent with the average column density of material traversed by cosmic rays, ~ 5 g cm^{-2} (as determined by measurements of products of spallation reactions), and the usually assumed average density of matter in the galactic disk (~ 1 H atom cm^{-3}).

Measurements of the interstellar density indeed show[3] $\rho_{\mathrm{is}} \sim 1$. The newly determined cosmic ray lifetime, however, implies that the average density through which the particles have travelled is ~ 0.2 atom cm^{-3}. This value is an upper limit to the average density encountered by cosmic rays in the galaxy at large, since there is evidence indicating that cosmic rays traverse a large fraction of the above mentioned column density at the particle sources[4]. It is therefore apparent that cosmic rays must spend $\sim 80\%$ of their lifetimes in regions of the galaxy where the density is significantly less than the average value found in the disk.

For this reason, the existence of a cosmic ray "halo" has been postulated[1,5]. This halo is a low-matter density region of cosmic ray confinement which surrounds the galactic disk.

Webster[6], however, analysed data concerning the radio halo of the galaxy, and found that the idea of static confinement in the halo is inconsistent with the observations. Dynamic confinement such as that proposed by Jokipii[5] may explain the low mean density traversed by cosmic rays.

An alternative explanation is proposed here. The low mean density traversed may be indicative of the presence of hot, low density tunnels in the interstellar medium such as those proposed by Cox and Smith[7]. Cosmic rays produced in supernovae or in supernova remnants are preferentially injected into these tunnels. The tunnels act as cosmic ray traps in which the density is low ($\sim 10^{-3}$ atom cm^{-3}), thus reducing the mean density encountered over the particle lifetime.

Many of the theories of the origin of cosmic rays involve particle acceleration by supernovae explosions, by the resultant pulsar, or in the supernova remnants. Analysis of cosmic ray abundances[8] supports the view that cosmic rays are accelerated, at least partially, in supernova remnants (compare with ref. 9 and J. R. Jokipii, personal communication). Indeed, γ-ray observations of the Vela supernova remnant[10] show that it is likely that supernovae or supernova remnants both produce and confine enough cosmic rays to explain the observed galactic cosmic ray density.

Cox and Smith[7] estimate that a fraction, f, of the volume of the interstellar medium is occupied by hot, tenuous tunnels caused by linked chains of supernova remnants, where $0.1 \lesssim f \lesssim 0.5$. Since typical remnants expand to a radius of ~ 40 pc before they start to disappear, they have a probability, P, of intersection with an existing tunnel, such that $0.6 \lesssim P \lesssim 1$. When the shock front of a new remnant encounters an existing tunnel, the shock is preferentially driven along the tunnel. Thus the remnant material which contains the cosmic rays produced by the supernova (Higdon and Lingenfelter's[10] data indicate that cosmic rays are confined up to a remnant radius of $\lesssim 30$ pc) is injected into the tunnel system.

As was pointed out previously[7], the tunnel systems are excellent cosmic ray traps, since they are regions of low magnetic field. The tunnels are intertwined about the large scale flux tubes of the galactic magnetic field. Particles injected into the system are therefore internally reflected by the high magnetic fields in the tunnel walls. The particles can escape only by slowly diffusing on to the galactic field lines.

The most likely mechanism of particle escape from the tunnel is resonant pitch-angle scattering with turbulent fluctuations in the interstellar field. The typical (~ 3 GeV) cosmic ray particle has a gyro radius $\sim 10^{12}$–10^{13} cm in the galactic field ($\sim 3 \times 10^{-6}$ gauss). Unfortunately, we have no observations of the scale size of the turbulence in this regime, and this makes it difficult to estimate the time scale of escape. It is, however, interesting to note that this mechanism will, if operative, give an energy dependence to the cosmic ray spallation products. This is because particles with different gyro radii (that is, different energies) will scatter most effectively off correspondingly different sized fluctuations, and the probability of encountering a given size fluctuation is generally a function of the size of that particular turbulent element. This effect produces a variation in the fraction of the lifetime of the particles which is spent in the high density regions of the disk, and thus a variation in the spallation products. Energy dependence of spallation products is indeed observed[11], although an alternative explanation has been suggested[9].

Measurements of the far-field resonance cone for whistler mode waves in a magnetoplasma

USING a large volume laboratory magnetoplasma the wave fields and resonance cone of the right hand polarised (whistler mode) wave have been mapped at distances of up to 10 whistler wavelengths from a transmitting antenna. The results are in good agreement with theory and suggest that energy is convected away from the antenna along the surface of the resonance cone. Considerable attention has been paid to the generation of waves by a point source in a magnetoplasma, and theoretical analyses[1–5] have shown that for certain combinations of the antenna operating frequency ω, the electron gyrofrequency ω_c, and the plasma frequency ω_p, the fields become singular along a cone whose axis is parallel to B_0, the steady magnetic field. By examining the refractive index surfaces it can be seen that the group velocity of the wave is zero when the ray vector is parallel to the resonance cone of half angle θ (when the wave normal is at an angle $\pi/2-\theta$ to B_0). We restrict ourselves here to a discussion of the radiation pattern for frequencies $\omega<\omega_c\ll\omega_p$. Waves launched by the antenna then propagate in the right hand polarised whistler mode and the angle of the resonance cone is approximately given by $\theta=\sin^{-1}(\omega/\omega_c)$.

This phenomenon is of particular interest because it defines a narrow region of space in a magnetoplasma where the group velocity is very small. The question then arises as to whether energy is, in fact, transferred along the resonance cone or is merely a near-field phenomenon. If the cone exists in the far field it would have a significant effect on the propagation characteristics of the wave and the impedance of the transmitting antenna. This information would be needed with any mother–daughter spacecraft experiment where the dispersion of a wave travelling between two spacecraft is interpreted in terms of the local plasma parameters. It is also needed in laboratory experiments on controlled thermonuclear reactions where radio frequency energy is used to heat the charged particles to high temperatures.

The behaviour of the cone angle as a function of ω, ω_0 and ω_p has been studied experimentally in the near field[5,6] and is reasonably well understood. The far field of the cone and wave fields have been studied theoretically[7] but little other work has been done on this part of the problem. In particular, the shape of the wave fronts in the cone and the propagation of energy along the cone surface are problems yet to be solved.

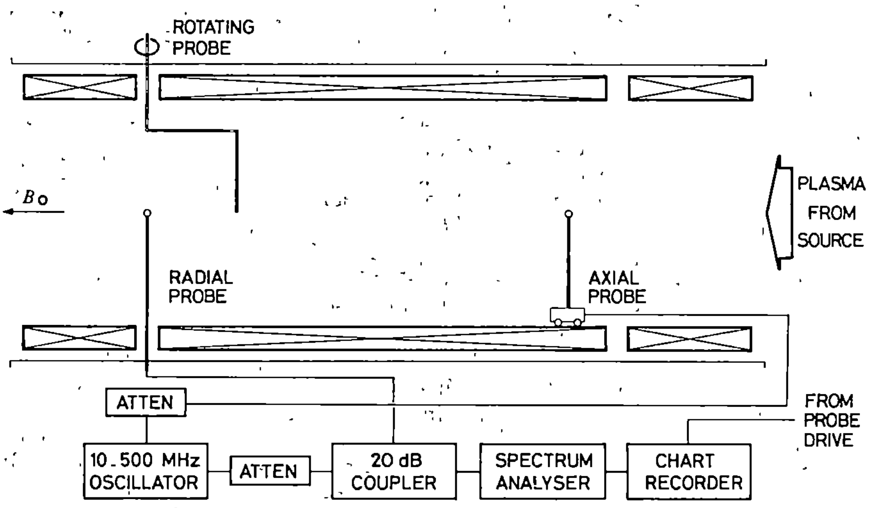

Fig. 1 Experimental arrangement of the solenoids and probes.

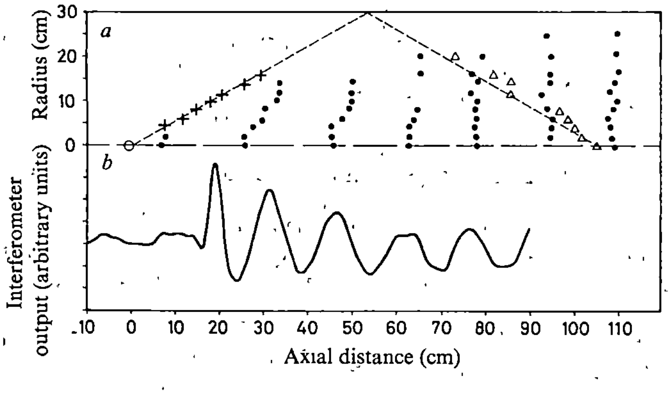
Using small, movable probes in a large, laboratory magnetoplasma, I mapped the radiation field of an antenna over a distance of up to 10 wavelengths of the whistler wave. For convenience, a frequency of about half that of ω_0 was used since it was thought that the focusing effect predicted by Wang and Bell[7] may be observable, although they investigated the very far-field radiation pattern at a distance of approximately 6,000 wavelengths.

Fig. 2 *a* Results derived from the interferometer measurements: crosses, positions of the resonance cone; triangles, positions of the cone after reflection from the wall of the vessel; dots, surfaces of constant phase of the whistler wave (each set is 2π in phase apart). *b*, An interferometer trace taken at a radial distance of 10 cm.



The experiment was performed in a large volume magnetoplasma[8], 60 cm in diameter and approximately 150 cm long. An axial magnetic field was provided by three solenoids giving an axial uniformity of ±0.6% over 120 cm and 0.01% uniformity over the central 10 cm. Fields of up to 300 gauss can be obtained (see Fig. 1).

A plasma was formed in a glass tube 15 cm in diameter at one end of the vacuum chamber by radio frequency ionisation at 80 MHz. The oscillator produced about 1 kW of radio frequency power which was coupled into the plasma inductively. The coupling between the source axial magnetic field and the main field allowed the plasma to drift into the experimental volume, producing a radial gradient in density, which was approximately Gaussian.

Langmuir probe measurements gave the electron temperature as 2.6 eV, in good agreement with results derived from measurements of the interference structure of the resonance cone[9]. For this experiment the magnetic field was set at 64 gauss, with an Argon gas pressure of 4×10^{-4} mmHg giving a collision frequency—essentially caused by electron—neutral collisions—of about 0.0005 ω_0. Any dissipative effects would, therefore, be of a collisionless nature.

By measuring the whistler wavelengths over two decades in frequency a graphical plot of the dispersion was obtained. This was compared with theoretical curves using ω_p as a fitted parameter, and yielded an average value for the electron density of 4×10^{10} cm^{-3}.

The transmitting antenna had a loop 1 cm in diameter at the end of a coaxial probe 3 mm in diameter which could be moved along the length of the vessel. Receiving antennae were similar loops or small electric probes with an exposed surface 1 mm in diameter and 4 mm long. The wave fields were mapped by setting the receiver at a certain radial position and moving the transmitter axially.

Since it was found that the resonance cone itself was reflected from the metal walls of the vessel, this method of moving the transmitter on the axis maintained symmetry and allowed the position of the reflected cone field to be determined easily.

A simple interferometer was constructed using the received signal as one arm and a direct signal from the oscillator driving the transmitting antenna as the other arm. The two signals were mixed and displayed on a spectrum analyser set to zero scan (that is, operating as a narrow band superheterodyne receiver) and a permanent copy was made on an *x*–*y* chart recorder.

Figure 2*a* shows results taken from interferometer traces using a loop receiving antenna for a frequency of 150 MHz

($0.47\ \omega_c$). The positions of the reflected cone, shown by the triangles, could be determined from the traces as a rapid change of phase which could be distinguished easily from the whistler wave fields. For this particular wave frequency the theoretical cone angle is 28°, in good agreement with the experimentally measured value of $28 \pm 1°$.

At higher magnetic fields, B_0, we have measured the resonance cone field at distances greater than 10 wavelengths from the transmitter, where the wavelength referred to is that for a longitudinally propagating whistler wave. This would seem to suggest that energy does in fact propagate along the cone surface away from the transmitter in contrast to the assumption of Wang and Bell[7] that the radiation intensity near the cone has little physical significance.

Within the cone, the wavefront can be seen to be curved. By examining the refractive index surface and constructing wavefronts, a theoretical wave front can be determined, and that is in good agreement with our measured results. Further away from the cone, the effects of the cylindrical geometry must be taken into account. As the diameter of the vessel is much larger than the wavelength, the dispersion of the waves is little changed but the shape of the wavefront is planar in cylindrical geometry and the gradual change from curved to planar can be seen in the figure.

A maximum variation of about 20% in wavelength along the axis shows that the axial gradient in density caused by the drifting plasma is probably of the same order of magnitude. The radial gradient in density does not seem to have any significant role in the formation of the wavefronts.

An interferometer trace using a loop receiving antenna taken at a radial distance of 10 cm is shown in Fig. 2*b*. The first maximum corresponds to the resonance cone and following maxima are caused by the wavefields. The nonzero signal to the left of the resonance cone is caused by the interferometer, the wave field outside the cone being essentially zero. By moving a probe radially, the wave fields were found to be greatest along the axis, decreasing gradually as the resonance cone is approached. Although we cannot regard this as a measurement of the focusing effect suggested by Wang and Bell[7], it is quite possible that after many more wavelengths the fields would be concentrated about the axis.

The increasing area of the wavefront as it moves away from the transmitter can be seen as a gradual decrease in the wave amplitude.

I am at present mapping the radiation fields and, in particular, the relative amplitudes phases and directions of E and H for a wide range of frequencies below the electron gyrofrequency, especially below $\omega = 0.2\omega_c$, where the ray direction can theoretically be outside the resonance cone. These results will be presented elsewhere.

Discussions with A. Gonfalone, D. Jones and A. Pedersen, and the technical assistance of H. Arends, are acknowledged. I also thank Professor T. Kaiser for useful suggestions and comments. I was an ESRO research fellow.

Subducted greywacke in the Olympic Mountains, USA—implications for the origin of Archaean sodic gneisses

IN Archaean greenstone belts the earliest granitic rocks are sodic or quartz dioritic gneisses and migmatites that surround and diapirically intrude the greenstones. The granitic rocks have been considered as the sialic basement on which the greenstones were deposited[1,2] and as sialic underplatings of a primordial greenstone crust[3–5]. But the structural relationships between greenstones and greywackes in the Olympic Mountains of Washington State, USA, suggest that the Archaean gneisses may have formed by subduction of greywacke suites and associated volcanic rocks beneath nearly coeval oceanic crust.

If the Archaean granitic rocks are primary sialic basement[1,2] the sodic gneisses must be older than, and beneath, the oldest Archaean greenstones. This possibility is attractive, since gneiss domes in younger terrains are generally regarded as remobilised basement rocks, and the sodic migmatites are compositionally similar to the diapiric plutons[4]. Contacts between the oldest greenstones and sodic granitic rocks are, however, invariably tectonic or intrusive. No unequivocal examples are known where the oldest greenstones lie unconformably over granitic basement[4–7]. Unconformities do exist within the Archaean, but the basal layers comprise sedimentary rocks, mostly conglomerates, resting on granitic rocks[6–8]. Further, 'granitic' clasts in Precambrian volcanic–sedimentary belts do not occur in the basal greenstones, and clasts higher up in the sequences may have been derived from nearly contemporaneous volcanic and hypabyssal rocks rather than from a pre-existing granitic basement[9].

The Archaean gneisses are, admittedly, of higher metamorphic grade and more highly deformed than the adjacent greenstone belts, but these criteria cannot be used reliably to establish the relative ages of suites that are tectonically juxtaposed. Within the Barberton greenstone belt of South Africa, the Swaziland Supergroup has been dated[4], using Rb/Sr techniques at 3,355 Myr and the surrounding Ancient Gneiss Complex[4] at 3,395–3,138 Myr. This coeval relationship holds for several Archaean greenstone and gneiss terrains[5].

The sodic granitic rocks have also been considered to be sialic underplating (without any supracrustal manifestations) of the primordial greenstone crust[2,4,5]. The granitic migmatic terrains, however, contain relict metasedimentary or metavolcanic features, such as banded iron formations, amphibolites, and quartzites[1,4–6]. If the tonalitic bodies within the migmatitic complex adjacent to the Barberton Greenstone Belt were anatectic additions to the gneisses, the resultant increase in volume should have deformed the neighbouring greenstone belt[4]. Moreover, the anatectic mechanisms necessary to generate vast amounts of sodic granitic material from oceanic crust or the mantle are somewhat difficult to envisage[1,3].

The Olympic Peninsula comprises two almost coeval lithological assemblages (Fig. 1). The mountain core is composed of Eocene–Miocene slate and greywacke with minor lenses of basaltic rocks. These core rocks are strongly folded and faulted and are metamorphosed in the prehnite–pumpellyite to lower greenschist facies[10].

Flanking the mountain core on the north, east, and south is a discontinuous belt of early (?) and middle Eocene marine basaltic rocks, which are succeeded by an Upper Eocene to Miocene marine sedimentary sequence. Although folded and faulted, this succession is generally stratigraphically continuous, and only modestly deformed compared with the core rocks The basaltic rocks of the

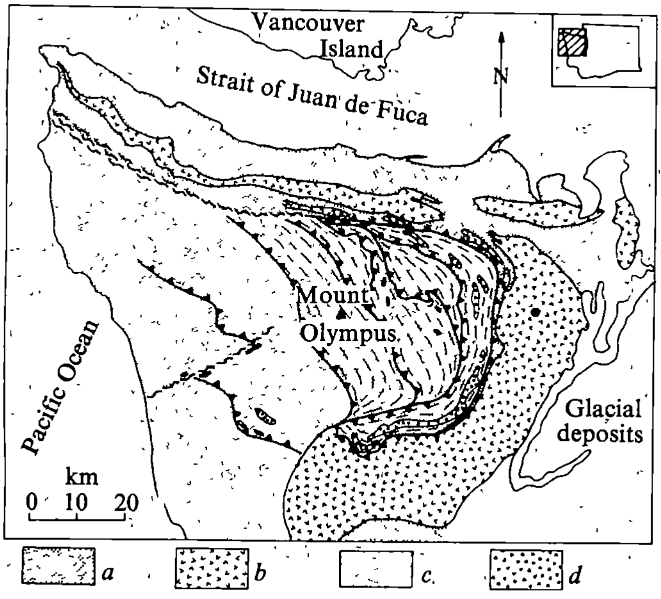

Fig. 1 Structural sketch map of the Olympic Peninsula, Washington (after Tabor[10]). *a*, *b*, Peripheral rocks (orderly, moderately deformed and partially metamorphosed): *a*, Eocene to Miocene sedimentary rocks; *b*, early (?) and middle Eocene volcanic rocks (basalt and greenstone). *c*, *d*, Core rocks (intensely deformed, faulted, and partially metamorphosed): *c*, Eocene to Miocene sedimentary rocks (dashed where penetratively deformed); *d*, Eocene and younger (?) volcanic rocks (basalts and greenstones). *e*, Contact; *f*, thrust fault; *g*, shear zone.

peripheral belt are dominantly pillowed and massive diabasic oceanic tholeiites[11,12], but about 20% are alkalic basalt[12]. An intrusive complex of diabase, gabbro, and porphyritic basalt occurs in the thickest portion of the basalts[12].

Chemically, most of the basalts correlate well with oceanic-ridge tholeiites, particularly in their TiO–FeO/MgO distribution and in rare earth elements, although some of the upper flows show trends typical of oceanic-island tholeiites[12]. Most of the volcanic pile is apparently a slice of upper oceanic crust, with the small volume of alkalic rocks representing the last phases of volcanism[12].

The volcanic rocks have been statically metamorphosed from zeolite facies to prehnite–pumpellyite and, locally, greenschist facies. Many of the flows "might well be called greenstones"[13].

The basalts crop out in an arcuate pattern starting on the north-western tip of the peninsula and extending more than 220 km east and south. Their thickness varies from a few tens of metres in the north-west to a maximum of 15 km on the east[11]. Regionally, these rocks are part of an early (?) to middle Eocene assemblage of marine basaltic rocks that extends from Vancouver Island southwards to the Klamath Mountains, a distance exceeding 600 km.

Structural and palaeontological relationships indicate that the greywackes and slates of the core are of the same age or younger than the basalts and that the core rocks were inserted beneath the peripheral basalts along a thrust mappable over a distance exceeding 120 km[11,14]. Regional gravity data[15] from the eastern portion of the Olympic Peninsula suggest that the basalts are a slab about 15 km thick, dipping 45 degrees eastwards.

The extreme deformation and thrusting of the core rocks under the peripheral basaltic rocks was probably the result of pre-Pliocene subduction. Subduction is indicated by the ages and patterns of linear magnetic anomalies in the adjacent north-eastern Pacific Ocean[16].

The few published analyses of K_2O–Na_2O ratios in Olympic core rocks[17,18] and the K_2O/Na_2O plots of Tertiary greywackes, Archaean greywackes, and Archaean sodic granitic gneisses[5] yield results of about 0.5. Thus, isochemically metamorphosed Tertiary or Archaean greywackes could yield rocks with the same K_2O–Na_2O ratio as Archaean sodic granitic rocks. This suggestion is an extension of the inference[19] that greywackes may be transformed isochemically in to banded albite schists and gneisses. Mineralogically, chemically, and in some cases even texturally, the sodic migmatites are very similar to the sodic diapirs that intrude the Barberton Greenstone belt[4]. The presence of basaltic rocks within the greywackes of the core of the Olympic Mountains and of amphibolites in the Precambrian migmatitic terrains is especially interesting in view of Glickson's comment that "Tonalites and granodiorites intruded into Archaean systems commonly abound in basic xenoliths . . .; such altered xenoliths represent remnants of basic rocks intruded by the acid melts thus pointing to an origin of the melts from below a basic crust."[3].

We concur with Anhaeusser[20] that plate tectonic models for Archaean time are viable, and suggest that the Archaean sodic granitic rocks may have been supracrustal rocks that were subducted beneath coeval oceanic greenstones. This hypothesis avoids the problems inherent in postulating a primordial sialic crust, the requirement of large scale anatectic granitic underplating of the greenstones, and the extreme lateral variations in geothermal gradients otherwise needed[5] to account for adjacent Archaean belts of vastly different metamorphic grades.

We thank W. R. Dickinson, B. M. Page, C. F. Park Jr, and R. W. Tabor for discussions. This work was supported in part by the National Science Foundation.

Plate tectonic significance of repeated tectonic trends in eastern Canada

THE existence of generally parallel, major tectonic structures of different ages has been long recognised. In Eurasia, for instance, the Alpine Orogenic Belt is paralleled by the Hercynian–Variscan Orogenic Belt, and in southern New Brunswick there is a general parallelism between the Alleghenian (Variscan) and Acadian fold belts[1]. In Newfoundland[2] the Acadian Fold Belt runs generally parallel to the older, late Cambrian–earliest Ordovician (Grampian) Fold Belt in the west and a pre-middle Ordovician fold belt in the east. Further, the Appalachian–

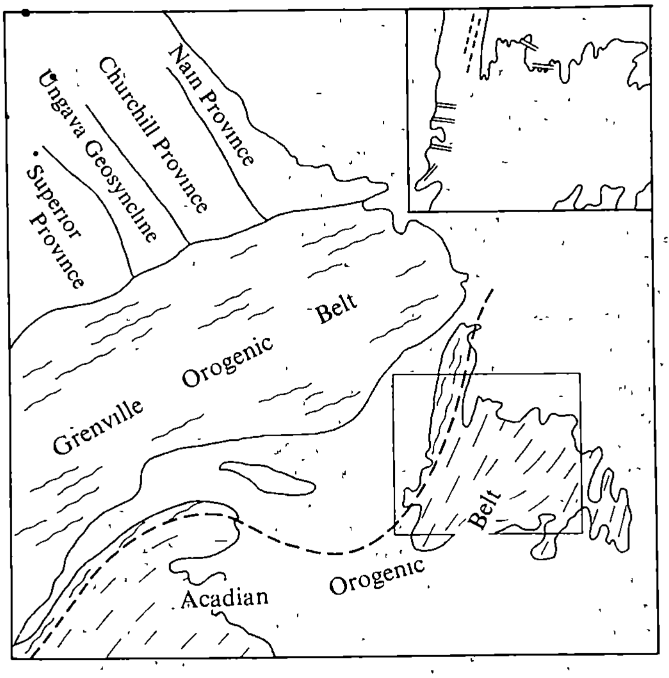

Fig. 1 Tectonic features of eastern Canada Inset (showing boxed area): dashed lines, dykes cutting the Grenville Province; solid double lines, sheeted dykes.

Caledonian Belt as a whole in north-eastern Canada runs parallel to the older (1,000 Myr BP) Grenvillian Orogenic Belt for at least 1,000 miles. These are clearly indications of continental accretion (Fig 1).

The Precambrian and Phanerozoic Belts which run parallel to the North American seaboard of the north Atlantic Ocean are terminated transversely by the Labrador Sea. Thus, in terms of pre-Mesozoic fit, the correlation of the Grenville Formation[3] with the British Isles is uncertain. The Caledonian and northern Appalachian Orogenic Belts, in spite of their apparent continuity from Newfoundland to the UK, are not of identical ages. The Caledonian Belt generally reached a climactic episode during end-Silurian-early Devonian times, whereas the northern Appalachian Belt was generally deformed during the mid-Devonian. An important factor in the interpretation of the cutoff against the Labrador Sea is the nature of the ophiolite complexes in Newfoundland. Dewey and Bird[4] have drawn attention to the significance of Newfoundland ophiolites as portions of old (early Ordovician and older) oceanic plate. Later work[5-8] resulted in a wider recognition that these ophiolite complexes could be remnants of Ordovician or older small oceans, with an internal structure of oceanic lithosphere, including basaltic pillow lavas, sheeted dykes, gabbros and upper mantle peridotites.

Dewey and Bird's model envisaged that the deformation of the sedimentary prism marginal to the continent was contemporaneous with the subduction of the oceanic crust. In this respect the oceanic crust of the small oceans in Newfoundland needs further study, as it includes some unexplained features. First, the fragments of oceanic crust lie tectonically over[9] or, at least, almost against the sialic crust[5]. Second, their internal structure cannot be related to the deformed sialic rocks since the sheeted dyke complexes are at a high angle to the trend of orogenic deformations (Fig 1, inset) The direction of the initial spreading of the preserved oceanic crust is thus not parallel to the direction of final closing (Fig 1, inset) of the ocean as a whole.

The relationship between the ophiolites and the adjacent continental rocks along the northern coast of Newfoundland can be interpreted in terms of obduction, rather than subduction. The trend of the dykes in the sheeted complexes suggests that the small ocean whose strike is indicated by the sheeted dyke complex, had a trend radically different from the larger ocean to which the Appalachian Orogenic Belt of Newfoundland was marginal. This larger ocean is often referred to as the proto-Atlantic[9]. It is significant that the trend of the Ordovician(?) sheeted dykes is sub-parallel to the present magnetic lineations of the Labrador Sea[10,11]. It seems reasonable to suggest that the small Ordovician ocean had the same relation to the proto-Atlantic as the present Labrador Sea has to the modern Atlantic Ocean. If that is so, then the preservation of parts of the small ocean (proto-Labrador Sea) could be explained by the hypothesis that, when the proto-Atlantic Ocean closed, a small, oceanic, proto-Labrador Sea became completely land locked. Similarly, were the modern Atlantic Ocean to close, one would expect the oceanic crust of the present Labrador Sea to be preserved at a high tectonic level and to obduct on to the adjacent Greenland–Canadian mainland. It would not subduct because it would be situated inside the subducting margin of the closing Atlantic Ocean.

The hypothesis has further implications, in so far as it suggests that a triple junction of the type that now exists at the meeting point of the North Atlantic Ocean, the north-eastern Atlantic Ocean and the Labrador Sea must have existed at approximately the same location during early Palaeozoic times. Thus, the cutoff of the Grenville Belt becomes more intelligible and the time difference between the Caledonian and Acadian orogenies is explicable by regarding the two branches of the orogenic belt as lying on opposing sides of the triple junction. Furthermore, the Labrador branch of the Ungava Geosyncline[12], deformed during the Hudsonian Orogeny, may have represented a margin to a still earlier 'Labrador Ocean' which existed there some 2,000 Myr BP. It is fitting to suggest a longevity of certain tectonic situations in geological time and the existence of lithospheric weaknesses which are repeatedly subject to separation and collision.

Mesospheric and lower thermospheric wind changes over Canada during the January 1975 stratospheric warming

EVIDENCE indicates that the mesosphere and lower thermosphere may be perturbed when stratospheric temperatures increase rapidly in winter Much of this evidence is indirect, due to limitations inherent in existing techniques of observation, and typically comprises measurements of ionospheric

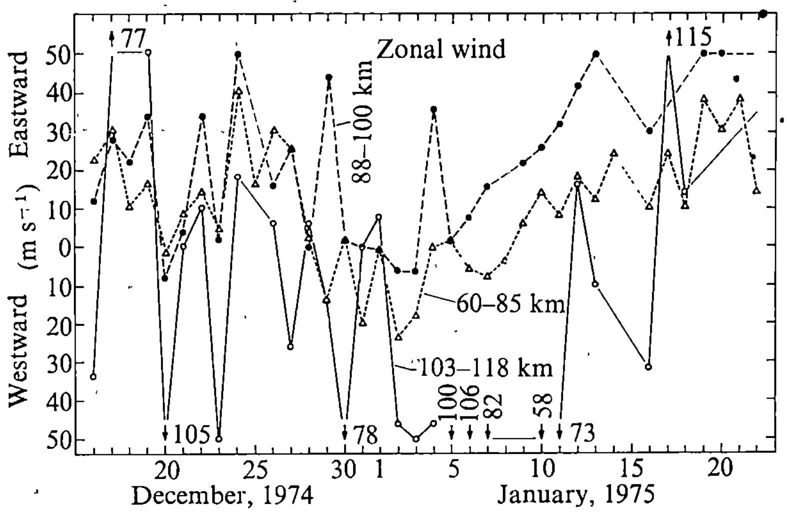

Fig. 1 Zonal component of daily median wind, for one hour around noon, and in the altitude ranges 60–85, 88–100 and > 103 km, at Saskatoon.

conditions, such as absorption in the lower ionosphere or heights of isoelectronic surfaces up to the E-region. Changes in these conditions are found to be significantly correlated with increases in stratospheric temperatures in winter at latitudes above ~40°.

There seem to be at least two related classes of stratospheric temperature changes. The first is an aspect of a travelling planetary wave—changes in the mesospheric electron densities associated with such waves have been observed in both the Southern Hemisphere[1], and Northern Hemisphere[2,3]. The second, which is usually called a stratospheric warming or a major warming, is the reversal, in winter, of the polar vortex to westward flow. It is thought to be initiated by the interaction of a travelling planetary wave with a standing wave[4,5]. Ionospheric changes related to major warmings have been identified in the Northern Hemisphere[6]. In the Southern Hemisphere, the interaction of travelling and standing planetary waves may not occur to the same extent as in the Northern Hemisphere.

Observations of the winds and temperatures of the mesosphere and lower thermosphere during stratospheric warmings are relatively few. Significant correlations between the temperatures at 30 km and the pressures at 55 km for Fort Greely, Alaska, and between temperatures at 30 km and pressures at 70 km for Wallops Island, Virginia[7] have, on occasion, been found. A reversal of zonal flow between 75 and 105 km, from eastward to westward, has also been observed in Alaska by means of the radio meteor technique during the warmings of the winters of 1967–68 and 1970–71 (ref. 8).

In the winter of 1974–75 observations of the winds from 50 to 105 km, were made near Saskatoon (52°N, 107°W) and Ottawa (45°N, 76°W), using the partial radiowave reflection, drift-of-diffraction-pattern technique[9]. Together with meteorological rocket measurements from Churchill (58°N, 94°W), these provide more detailed wind data with better continuity in the vertical direction, than previous experiments provided. The Churchill data (not shown) establish that a major warming was detectable around December 17, when the wind at altitudes between 30 and 40 km began to shift from eastward through southward, to a reversed (or westward) flow, which prevailed on January 9. On those dates, temperatures at altitudes between 30 and 40 km were ~ −60 °C and ~ −30 °C respectively. The flow remained westward until about January 17. For comparison, Fig. 1 shows the behaviour of the zonal component of winds at Saskatoon in three altitude ranges: 60–85, 88–100, and ⩾103 km. (The height at which total reflection of radio waves at 2.2 MHz is observed, occurs in the latter range.)

Five-year mean values (J. B. Gregory and A. H. Manson, unpublished), have established that the zonal component is normally eastwards up to ~ 95 km at this time of year, in the absence of perturbations caused by warnings. Above 95 km, the flow is normally westwards, and a westward component of the thermal wind, corresponding to a warm high-latitude mesosphere, also normally exists above 75 km during this part of the winter at Saskatoon. Figure 1 shows two forms of departure from this. The first is a short term variability, over intervals of 1–4 d, and is greatest above 100 km. This variability is believed to be due to the effect of gravity waves ($\tau \sim$ 60 min) when, because of incomplete data, they are not removed by height and time averaging The second departure, evident between about December 30 and about January 12, is of interest here, since it coincides with the warming observed at Churchill.

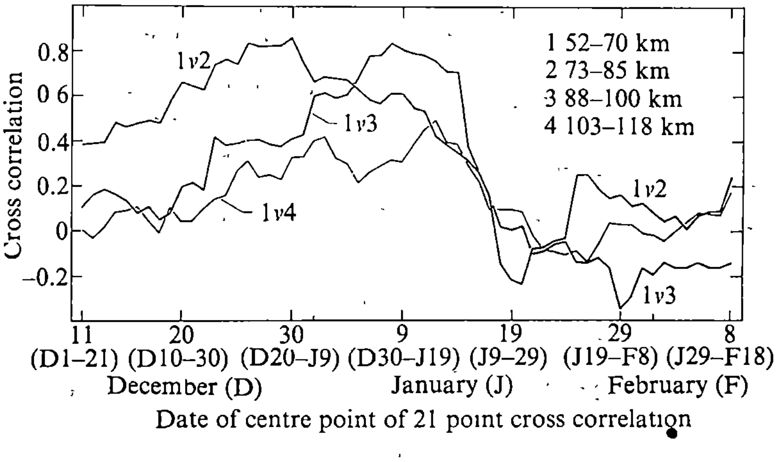

Fig. 2 Cross-correlation coefficients of zonal component of winds at Saskatoon, between four altitude ranges 52–70, 73–85, 88–100 and 103–118 km.

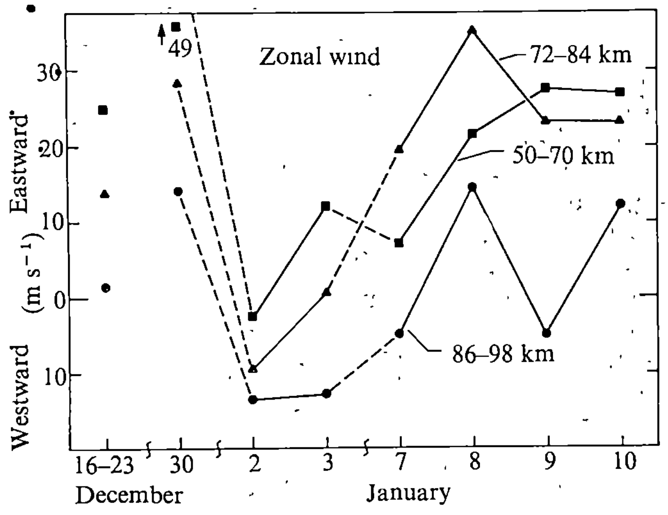

Fig. 3 Zonal component of daily median wind, around noon, in the altitude ranges 50–70, 72–84 and 86–98 km, at Ottawa: (Note the breaks in the sequence of dates.)

By January 1, the zonal wind below 95 km had reversed (and now blew to the west), and the flow above 95 km also altered significantly (Fig. 1). By January 5, recovery had commenced, though to reach speeds lower than before the warming. (A second warming was observed in early March, but is not discussed here.)

The extent to which wind changes at various altitude intervals are related, is demonstrated in Fig. 2. From the daily sequence of observations at Saskatoon, 21-d sequences have been selected, each starting a day after the previous sequence. Cross-correlation coefficients have been computed between the lowest altitude interval, 52–70 km, and successively higher intervals, for each 21-d sequence, with zero relative delay. (Coefficients of value 0.41 are significant at the 5% level, and those of value 0.53 at the 1% level.) The sequence of correlation coefficients shows that coupling existed between altitude intervals up to 85 km by about December 17, and to 100 km around the period of maximum stratospheric change, January 9–17.

Observations at Ottawa also show the effects of the warming. For present purposes, only those observations between December 30 and January 10 are considered. Figure 3 shows the mean zonal speeds, in three height ranges, 50–70, 72–84 and 86–98 km, derived from 40-min records around noon. This figure shows that reversal of the zonal flow, 50–98 km, occurred between December 30 and January 2, and that the initial flow was not resumed until January 8. These dates agree substantially with those for Saskatoon and Churchill.

Our observations, together with others at Saskatoon for the winters 1969–74, and the Alaskan observations[8], show that changes in mesospheric and lower thermospheric winds can be expected during stratospheric warmings, as can, presumably, temperature changes. Aeronomical changes are undoubtedly a consequence of these dynamical changes. In future studies, simultaneous observations of both dynamical and aeronomical conditions, on a spatial scale adequate to establish transport effects, will be required.

We are grateful to Dr R. S. Quiroz, National Meteorological Centre, for early access to Churchill meteorological rocket data.

Cavitation damage in dilute polymer solutions

HERE we report that the addition of small quantities of high molecular weight, water-soluble polymers to water (in our case polyacrylamide) increases the rate of vibratory cavitation erosion of copper. This result, together with that of Kudin[1], who obtained an enhanced rate of jet cutting after a similar addition, strengthens the analogy drawn between the two processes, and indicates that microjets may play a significant role in cavitation damage. These results may well be relevant for rain erosion, a process often compared with cavitation and jet cutting.

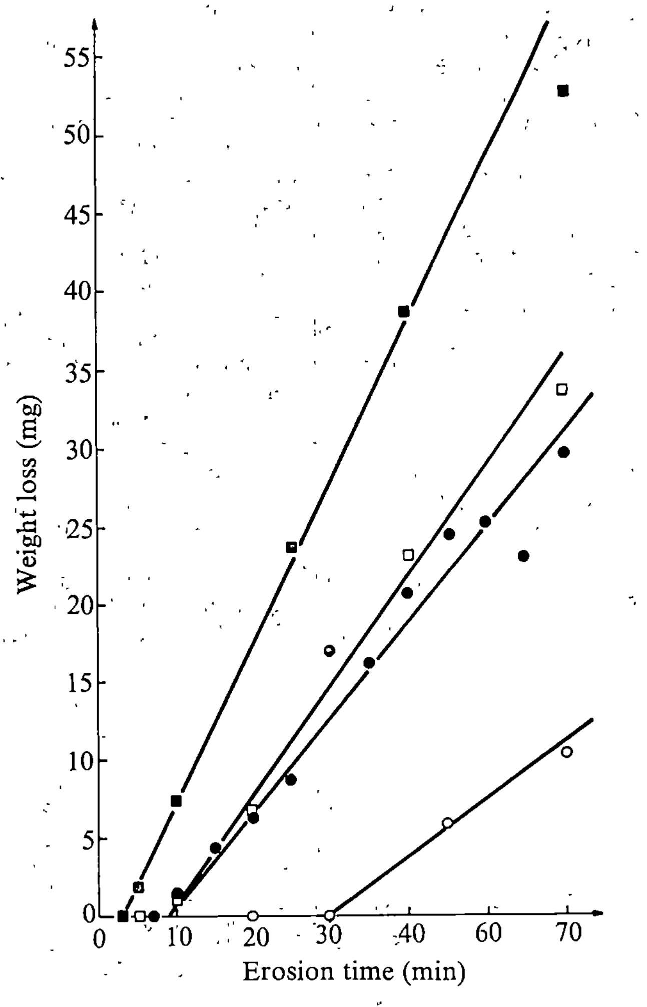

Fig. 1 Curves of vibratory cavitation erosion weight loss as a function of time for copper specimens in: ●, distilled water; □, equilibrated 100 w.p.p.m. polyacrylamide solution; ■, equilibrated 1,000 w.p.p.m. polyacrylamide solution; ○, 2:3 v/v glycerol–distilled water mixture.

Table 1 Experimental details

Solution	Conductivity (μS) (1 Siemen = 1mho)	*p*H	Viscosity (cpoise)	Surface tension (dyne cm^{-1})
Distilled water	3.0	5.5	0.89	72.5
Fresh 100 w.p.p.m. polymer solution	8.7	5.5	2.14	72.7
Equilibrated 100 w.p.p.m. polymer solution	9.7	—	1.31	—

Fresh 1,000 w.p.p.m. polymer solution	—	—	(26)	73.5
Equilibrated 1,000 w.p.p.m. polymer solution	4.5	5.1	3.85	71.0
Fresh 200 w.p.p.m. polymer solution*	—	—	4.05	—
Glycerol–distilled water mixture (2:3, v/v)	10.5	6.0	3.99	68

*These data are included for comparison purposes, to give an indication of the extent of polymer degradation, in terms of loss of viscosity.

Kudin's result[1] seemed to be of particular relevance to the mechanism of cavitation erosion of metals, since one model suggests that damage occurs as the result of the asymmetric collapse of cavities, leading to the formation of high velocity microjets which impinge on, and erode the metal surface (for example, refs 2 and 3). In view of their effects on jet cutting efficiency, it would therefore be anticipated that the presence of these polymers in a cavitating liquid would result in increased cavitation erosion. It has been shown in water tunnel experiments of Ting[4], however, that polyethylene oxide in tap water inhibits the inception of cavitation. Although this result does not give any indication of the effect on the rate of erosion once cavitation is produced, he[4] further suggests that, after the onset of cavitation, the asymmetric collapse of cavities and the formation of liquid microjets will also be retarded. It is postulated that this would be the result of increased resistance to flow, created by the viscoelasticity of the polymer solution[5]. If this latter suggestion is correct, it would be anticipated that the addition to cavitating liquids of soluble polymers, with appropriate viscoelastic properties, would result in decreased cavitation erosion.

It should be noted that an alternative model suggests that cavitation erosion is caused by the shock waves which result from the approximately symmetrical collapse of bubbles. It can be shown, however, that any increase in viscosity should have a damping effect on the rates of cavity growth and collapse. This would tend to reduce the magnitude of the shock wave, and to result in a decreased rate of cavitation erosion.

The cavitation experiments were undertaken on cold-drawn OFHC copper; the specimens used were disks, 19 mm in diameter and 6.4 mm thick, which were mechanically polished with 6 μm diamond paste. The tests were carried out in distilled water, and in solutions containing 100 w.p.p.m. and 1,000 w.p.p.m. of a water-soluble polyacrylamide (Percol 139, an anionic copolymer of acrylamide and 5% acrylic acid) with a mean molecular weight of about 10^7. Cavitation was produced by an ultrasonic probe (frequency 20 kHz) positioned immediately above the stationary copper specimen. In all tests, the titanium tip of the probe was 35 mm below the surface of the test solution, the amplitude of vibration was 60 μm, and the separation was 1.3 mm. The bulk temperature of the test solution was maintained at 298 ± 1 K, but no attempt was made to exclude air.

Preliminary experiments showed that the polymer in solution was partially degraded by extensive exposure to cavitation. A continuously refreshed liquid system, with a flow rate of 10^{-4} m^3 min^{-1} into a test vessel with a capacity of 2×10^{-3} m^3, was therefore used. By this means an 'equilibrium' solution, with a constant viscosity, was obtained. Before the start of each cavitation run, the initial solution in the test vessel was degraded to the equilibrium viscosity by means of cavitation in the absence of the copper specimen. The viscosities of the polymer solutions used, before and after equilibration, are reported in Table 1.

Figure 1 shows the cavitation erosion weight loss–time curves for copper in distilled water, and in equilibrated solutions containing 100 w.p.p.m. and 1,000 w.p.p.m. polyacrylamide. With the exception of relatively long exposure times, the effect of

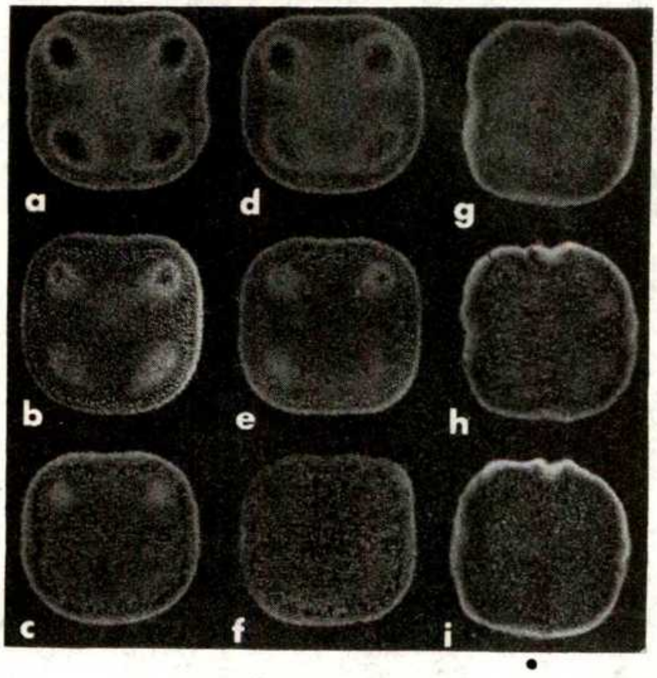

Fig. 2 Surface appearance of copper specimens after vibratory cavitation erosion in: *a*, distilled water for 10 min; *b*, distilled water for 20 min; *c*, distilled water for 60 min; *d*, equilibrated 100 w.p.p.m. polyacrylamide solution for 10 min; *e*, equilibrated 100 w.p.p.m. polyacrylamide solution for 20 min; *f*, equilibrated 100 w.p.p.m. polyacrylamide solution for 60 min; *g*, equilibrated 1,000 w.p.p.m. polyacrylamide solution for 10 min; *h*, equilibrated 1,000 w.p.p.m. polyacrylamide solution for 20 min; *i*, equilibrated 1,000 w.p.p.m. polyacrylamide solution for 60 min. Magnification ×2.2.

100 w.p.p.m. polymer additions is negligible. It is clear, however, that in the case of 1,000 w.p.p.m. polymer additions, the incubation time is reduced from ~ 8 to ~ 3 min, and the rate of weight loss is increased by a factor of ~ 1.4. These quantitative observations are confirmed qualitatively by the surface appearance of the specimens after erosion for equivalent times in the three liquids, shown in Fig. 2.

The data presented in Table 1 indicate the extent to which the polymer additions increase the viscosity of distilled water. It is widely accepted that, in the absence of other overriding factors, an increase in viscosity of the cavitating liquid results in less severe cavitation damage[6,7]. This effect has been confirmed for the present experimental conditions by undertaking cavitation tests on pure copper in a 2:3 (v/v) glycerol–distilled water mixture, which has a viscosity comparable with that of an equilibrated 1,000 w.p.p.m. polymer solution. The results of these experiments are also shown in Fig. 1. The increase in viscosity associated with the addition of glycerol to distilled water, increased the incubation time to ~ 30 min, and decreased the erosion rate by a factor of ~ 0.6 compared with that observed in distilled water. These data clearly confirm that the increased damage associated with polyacrylamide additions cannot be due to an increase in viscosity.

The data shown in Table 1 also indicate that the addition of soluble polyacrylamide does not significantly affect the surface tension of distilled water. The importance of these data lies in the fact that it has been shown that a marked decrease in surface tension, produced by the addition of a detergent, can also increase cavitation damage (V. A., D. Hulse, and R. P. M. P., unpublished).

Our result with additions of 1,000 w.p.p.m. polymer is in direct contrast to the theoretical predictions of Ting[4], but is fully consistent with the observed effect of such additions to jet cutting solutions.

The above results give no indication as to the mechanism by which the addition of polyacrylamide increases cavitation damage. It should be noted that, although the polyacrylamide does not significantly affect the surface tension of the solutions, it does increase markedly their viscosity. It has been shown experimentally, however, that an equivalent increase in viscosity, produced by the addition of glycerol, greatly decreases cavitation damage. Clearly, whatever the mechanism by which polyacrylamide additions increase cavitation damage, it is sufficient, in the case of the 1,000 w.p.p.m. solution, to outweigh the decrease in cavitation damage which would be expected on the grounds of viscosity alone. In the case of the 100 w.p.p.m. solution, it is possible that the two opposing effects balance each other.

Anomalous thermal behaviour of induced phosphorescence in irradiated, doped polymeric glasses

WE report here that the intensity of induced phosphorescence in pre-irradiated, doped polymethylmethacrylate (PMMA) glasses changes in an anomalous way with temperature. At room temperature the irradiated part of the sample shows intense phosphorescence after ultraviolet excitation with an inspection lamp[1], whereas the part of the sample not previously irradiated shows no afterglow. When, however, the sample is cooled to the temperature of liquid nitrogen and the ultraviolet photoexcitation is repeated, the irradiated spot appears dark on the bright afterglow background of the rest of the sample (Fig. 1*a* and *b*). In Fig. 1*a* the central, ultraviolet irradiated, spot is seen as a bright

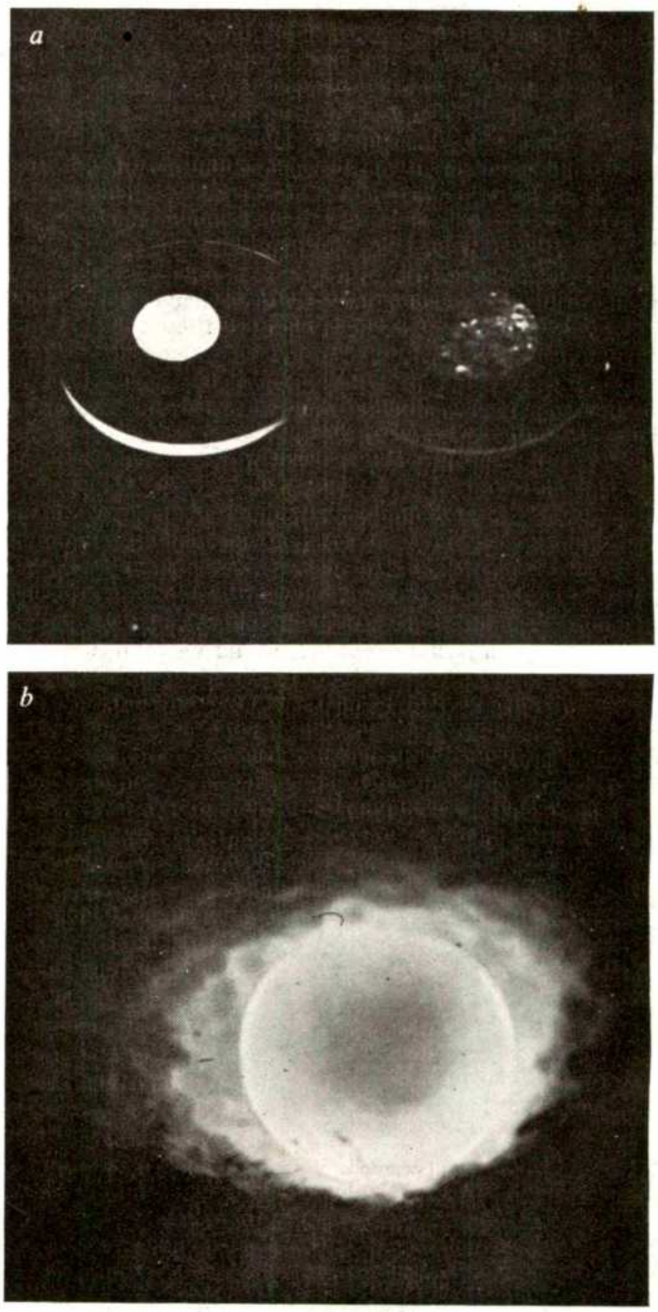

Fig. 1 *a*, Phosphorescence at room temperature after ultraviolet excitation has been switched off: left hand side, an X-ray irradiated sample; right hand side, an ultraviolet irradiated sample. X-ray and ultraviolet irradiated regions show clearly emission in the central areas of the samples; some of the emission is transmitted to the edges by a light guiding effect of the plane surfaces of the samples. The regions in the outer portion of the samples were not pre-irradiated and do not show room temperature luminescence. *b*, Phosphorescent glow in sample on the right of Fig. 1*a*, after it had been immersed in liquid nitrogen and the ultraviolet excitation had been switched off. The central area, which had been pre-irradiated with ultraviolet radiation, shows less phosphorescence than the area which had not been irradiated. As in Fig. 1*a* some light leakage is seen around the rim of the sample and in the liquid nitrogen.

circular region at room temperature after excitation with an ultraviolet inspection lamp; Fig. 1*b* shows the same irradiated spot, now relatively dark, after the sample has been cooled to 77 K and excited by the same inspection lamp.

Triphenylene is a convenient dopant because of its long triplet lifetime, 16 s, compared with dibenzothiophene which has a shorter lifetime of 1.5 s. Samples containing coronene as the dopant in PMMA after ultraviolet irradiation also show similar photographic results at room temperature and at low temperatures; visual inspections, using several dopants including dipbenzothiophene, dibenzothiophene sulfone and dibenzofuran have confirmed this. Quantitative studies have also confirmed that the induced phosphorescence shows an anomalous temperature–intensity relationship. The variation in the peak intensity of phosphorescence (measured at 462 nm) over a range of temperatures down to 188 K, for samples of non-irradiated polymethylmethacrylate doped with dibenzothiophene is shown in Fig. 2*a*. The curve is typical of those obtained for a number of different samples; because of variations in the thermocouple position slight shifts have been observed in the curves. The curves exhibit behaviour typical of normal phosphorescence in doped, organic glass matrices[2]. The accepted explanation of this effect is that as the temperature of the system is lowered the probability that non-radiative deactivation of the lowest triplet state (T_1) to the lowest state (S_1) will occur is reduced. This reduction is much greater than the reduction of energy transfer between higher singlet levels or between the first excited singlet state and the lowest triplet state. There is, therefore, still an appreciable energy transfer taking place between S_1 and T_1 so as to enable a certain number of triplet levels to be populated. These will then be emptied, increasingly, by radiative transitions, and thus phosphorescence is observed.

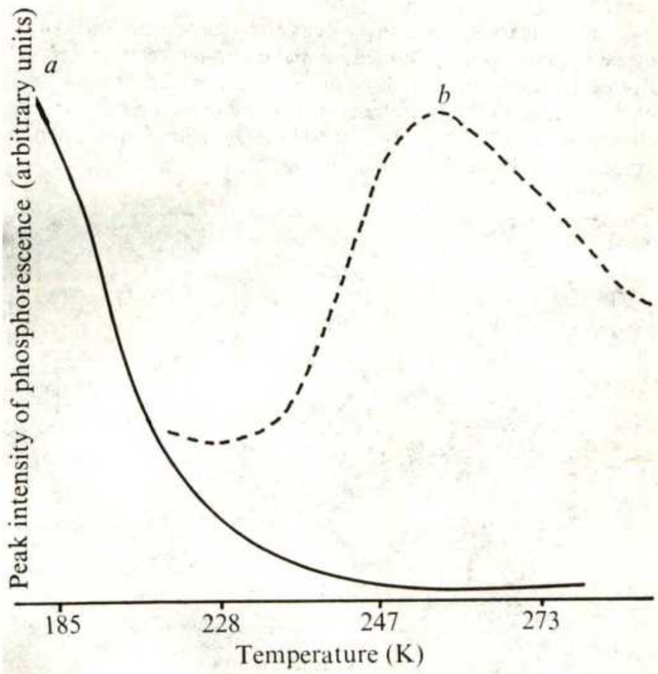

Fig. 2 *a*, Peak intensity of phosphorescence against temperature for a non-irradiated sample of doped PMMA; *b*, induced intensity of phosphorescence against temperature for an irradiated, doped sample of PMMA.

The behaviour of the induced phosphorescence peak of ultraviolet irradiated polymethlmethacrylate doped with dibenzothiophene is shown in Fig. 2*b*. Curves from a number of similar experiments show slight shifts in maxima; this is probably caused by variations in the position of the thermocouple with respect to the emitting surface. The main distinctions between Fig. 2*a* and *b* are, first, a non-irradiated sample does not show room temperature phosphorescence, whereas an irradiated sample shows an appreciable intensity of phosphorescence at room temperature; second, unlike the non-irradiated sample, the intensity of phosphorescence of the irradiated sample does not continue to rise as the temperature is reduced; it shows a maximum in the region of 250 K, after which the intensity falls as the temperature is further reduced. At about 228 K the intensity of phosphorescence of the irradiated sample falls to a value that is about the same as that of the non-irradiated sample. Further it does not show a marked increase as the temperature continues to be reduced to 185 K. This is contrary to the behaviour of non-irradiated samples.

A full explanation of this behaviour cannot be given at present; however, some of the features can be explained. Three temperature regions can be identified. Region I, from room temperature down to approximately 240 K, starts with significant phosphorescence at room temperature and increases to a maximum. We have postulated[1,3,4] that radicals or traps derived from PMMA, are involved in energy transfer from PMMA to the triplet state and that there is no exclusive requirement for population through the excited singlet state of the dopant. If it is assumed that all non-radiative processes diminish as the temperature is decreased, then curve *b* (region I) in Fig. 2 is consistent with the usual temperature behaviour for phosphorescence in photoinert matrices. The intensity in PMMA, moreover, is very substantially higher because of direct population of the triplet state bý energy transfer. In temperature region II, from approximately 240 K down to approximately 230 K, the induced phosphorescence decreases sharply, in contrast with the behaviour for a photoinert matrix. Assuming, as is reasonable, that the rates of the radiative processes are unaffected, but that the non-radiative decay processes are slightly decreased, it seems that energy transfer between the PMMA radicals and the triplet levels is involved.

The energy transfer which seems to diminish considerably in region II may be affected, possibly by the progressive freezing out of the diffusional mobility of the radicals or, more probably, by a reduction in the extent of the appropriate geometrical orientation of energy transfer partners. PMMA is known to have a γ transition at 268 K, attributed to hindered rotation of the ester group[5]. Temperature range III, below 230 K, shows a slight increase in phosphorescence. It can be assumed that energy transfer has been reduced to a minimum and the increase would then correspond to the further reduction of non-radiative processes from the triplet level. The intensity then lies below that for a photoinert matrix and much of the input energy is therefore degraded in the matrix (Fig. 2).

The enhancement of phosphorescence at room temperature is a striking and useful phenomenon though it does not persist below 230 K in this particular system.

Measurements of erythemally effective ultraviolet radiation and total ozone content

MEASUREMENTS of erythemally effective ultraviolet radiation—wavelengths between 290 and 320 nm—are now being made at Aspendale (38°S, 145°E) and Brisbane (27°S, 153°E) as part of separate studies being undertaken by research groups in Australia and the USA. The following preliminary analysis of these measurements supplements the theoretically calculated relationships[1-4] between the total atmospheric ozone content and the intensity of ultraviolet radiation incident at the Earth's surface.

The data were obtained at Aspendale between May 1966 and February 1970, using an instrument described by Robertson[5], and between June and August 1974 with two instruments—one described by Urbach *et al.*[2] and one developed by CSIRO; the Brisbane data were obtained between May and July 1974, also using the instrument of Urbach *et al.* The three instrument types are similar in operation, and have almost identical spectral responses. Each unit prints the half-hourly totals of integrated erythemal effectiveness of the ultraviolet radiation. The present analysis was performed for cloudless days only, and these days were selected from continuous records of global and diffuse short-wave radiation at Aspendale, and from visual reports of cloud cover at Brisbane. For each set of data listed in Table 1, a graph showing the daily maximum half-hourly total of ultraviolet radiation (the solar noon ultraviolet irradiance) was plotted against time, and a line of best fit drawn by eye. The graph for Aspendale is shown in Fig. 1*a*. In addition, graphs were plotted of the mean annual variation of total ozone content, from eighteen years of data for both Aspendale and Brisbane. The Aspendale curve is shown in Fig. 2*b*. The departures of both total ozone content and the noon ultraviolet irradiance from their mean values, were then expressed as percentages, and plotted against each other as in the example of Fig. 2 for Aspendale 1966–70. A line of best fit was computed using a method of least squares, in which the ozone and ultraviolet measurements were assumed to have similar relative errors[6]. For each set of data, the slope of the line of best fit is a measure of the change in the ultraviolet irradiance, which results from a change in total ozone content. These measured dependences are given in Table 1.

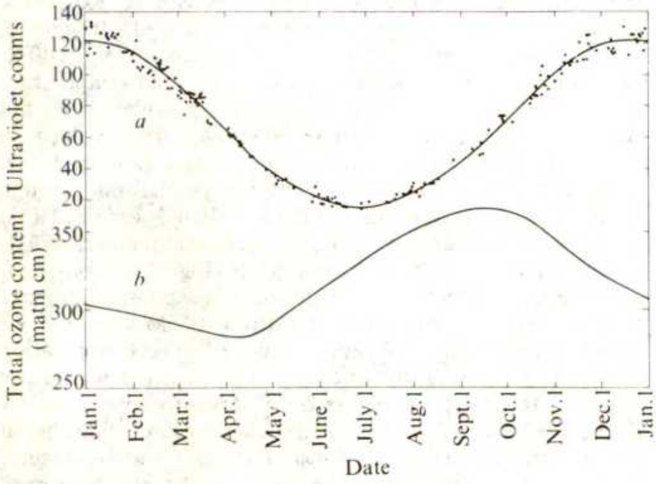

Fig. 1 *a*, Maximum half-hourly ultraviolet total for clear days at Aspendale, May 1966–February 1970. *b*, Mean annual variation of total ozone content at Aspendale.

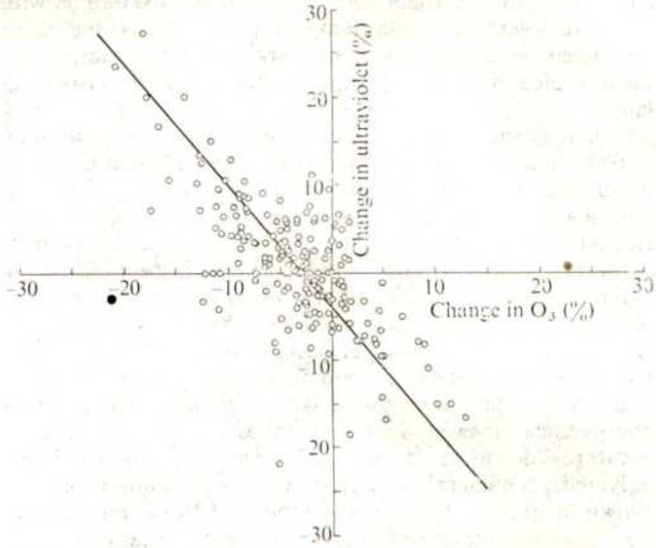

Fig. 2 Percentage change of ultraviolet intensity from the mean value as a function of percentage change of ozone content from the mean value. The graph is for the Aspendale (1966–70) data. ———, Line of best fit.

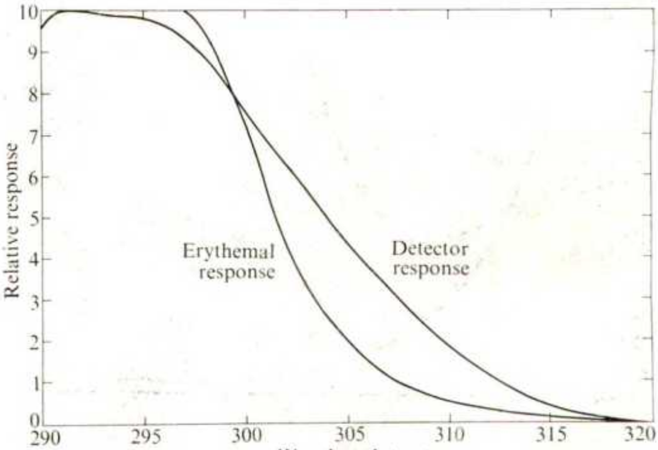

Fig. 3 The spectral response of the detectors. and the erythemal response of human skin.

In the table, the measured dependences are compared with those calculated using the equations and semi-empirical parameters of Green *et al.*[7]. These equations and parameters, which are based on the results of Bener (unpublished) give the ultraviolet irradiance at individual wavelengths in the range 280 to 340 nm as a function of solar zenith angle and total ozone content. The expected increase in 'measured' irradiance, for a total

Table 1 Results of clear day analysis

Location	Period	Instrument	No. of cloudless days	Ultraviolet dependence on total ozone content* Measured	Calculated Detector	Calculated Erythemal
Aspendale	May 66–Feb. 70	Robertson[5]	184	−1.40	−1.4	−1.7
Aspendale	June 74–Aug. 74	CSIRO	18	−1.32	−1.6	−1.8
Aspendale	June 74–Aug. 74	Urbach *et al.*[2]	22	−1.36	−1.6	−1.8
Brisbane	May 74–July 74	Urbach *et al.*[2]	31	−1.03	−1.4	−1.6

*The figures given are the ratios of percentage change in ultraviolet radiation intensity to percentage change in total ozone content.

ozone decrease of 10%, was then obtained by combining the calculated spectral irradiance with the spectral response of the detectors (Fig. 3). In addition, the dependences of erythemally effective ultraviolet irradiance on the total ozone content were calculated as above, but using the actual erythemal response curve given in Fig. 3. For the Aspendale 1966–70 data there is excellent agreement between the measured and calculated values. The other three periods of measurement give less satisfactory agreement, presumably because of the limited amount of data.

The Australian monitoring network now includes four stations; and further stations are planned. The importance of such long term monitoring programmes in this band of radiation is shown by the recent concern regarding the effects of possible anthropogenic modification of the stratospheric ozone layer (see, for example, ref. 8).

Movement of the hyoid apparatus during chewing

The movements of the hyoid bone and the larynx during swallowing are only well established for man[1–3]. Their movements, if any, during mastication in man and in other mammals have been neglected. The hyoid is suspended from the cranium, above and behind, by the posterior suprahyoid muscles (stylohyoid and the posterior belly of digastric) and from the symphyseal region of the jaw in front by the anterior suprahyoid muscles (anterior belly of digastric, mylohyoid, geniohyoid and the more inferior fibres of genioglossus). The infrahyoid, or 'strap' muscles of the neck connect the hyoid with the sternum directly by the sternohyoid and indirectly through the thyroid cartilage of the larynx (thyrohyoid and sternothyroid) as well as with the scapula (omohyoid). This arrangement of the hyoid apparatus is found in all mammals, except that the digastric may not have a direct hyoid connection[4]: a situation occasionally found in man[2]. These three groups of muscles (anterior and posterior suprahyoids and infrahyoids) are recognised, on the basis of anatomical, cinematographic[5] and electromyographic[6] studies of human deglutition, as acting in combination first to elevate and then to depress the hyoid and larynx in swallowing. The posterior suprahyoids and the infrahyoids are also classically regarded[1,2] as acting to "stabilise"[1] or "fix"[2] the hyoid so that the anterior suprahyoids, and particularly the anterior belly of digastric[6,7], can pull the symphyseal region of the jaw towards the hyoid and open the mouth. Mandibular depression follows the power stroke[8] of every chewing cycle. The classical view of the hyoid apparatus is of a somewhat immobile bone and a group of muscles whose only active role is in swallowing. This concept may have led to the view that, since the omohyoid in man made such an uncertain contribution to hyoid movement or control of hyoid position, a "specific"[1]

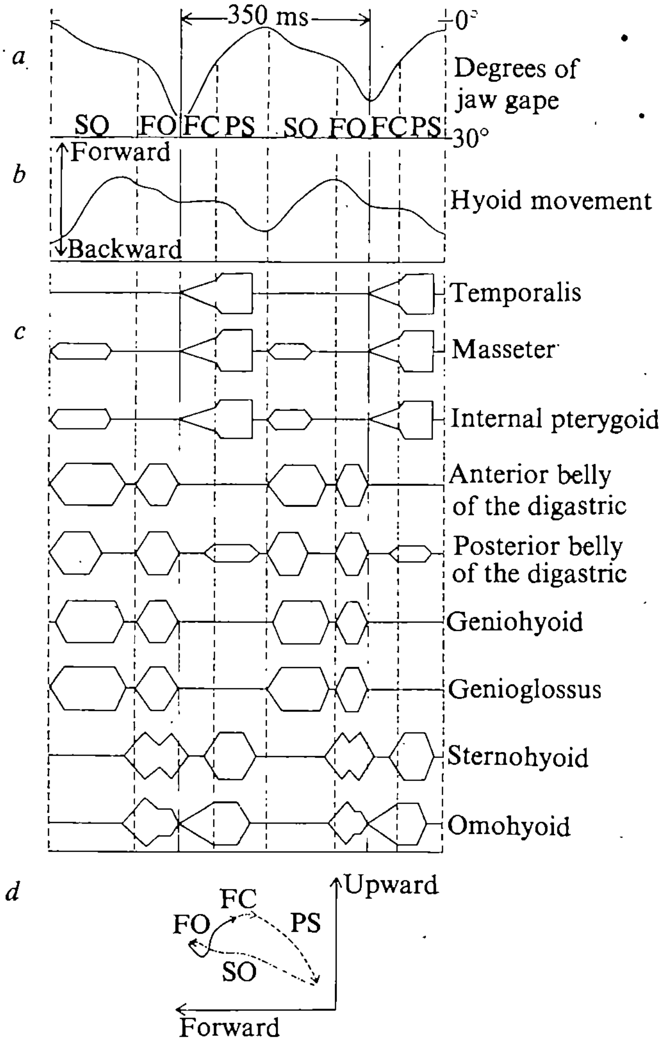

Fig. 1 Jaw and hyoid movement (*a*, *b*) in the opossum during part of a typical sequence of chewing on soft food. In *a*, the relative movement of upper and lower jaws has been plotted as degrees of gape (vertical axis) against time (horizontal axis). Each chewing cycle has four stages: FC, fast closing; PS, power stroke, (in this case consisting almost entirely of a slow closing movement); SO, slow opening; and FO, fast opening. In *b* the movements of the hyoid bone have been plotted on a plane parallel to the secondary palate; the range of antero-posterior movement is of the order of 20 mm. The associated EMG activity in adductor and representative hyoid muscles is shown in *c* as the envelope of the electrical signal. *c*, Composite diagram based on data from a large number of experiments. The path of movement of a point on the hyoid during chewing is shown in *d*. The diagram was obtained by plotting the position of the point in the 'vertical' and 'horizontal' planes (with reference to the hard palate, see text) at equal intervals of time during the cycle shown in *a*. Small skin incisions were made in anaesthetised animals so that bipolar wire EMG electrodes[9] could be inserted into the jaw elevators[10] and the major hyoid muscles (both bellies of digastric, geniohyoid, genioglossus, sternohyoid and omohyoid) under direct vision. On recovery, the animals were fed a minced proprietary canned dog food. Cinefluorographic recordings of jaw and hyoid movement were made in the lateral projection at 60 frames s^{-1} on 16-mm film[8]. EMG activity was recorded simultaneously on magnetic tape, together with a frame-by-frame synchronisation signal from the cine camera. The position of the jaws was measured on each frame of film as degrees of gape[11]. The position of the hyoid was measured separately in both the vertical and antero-posterior planes: for the former, the palatal line was used as a reference plane and for the latter, a perpendicular from that plane through the squamo-dentary joint. The tape recordings of the EMG activity were then converted into paper records and the positions of both the jaw and the hyoid were plotted on to these records: the data from each frame of film were registered against each synchronisation signal and a movement profile obtained.

and "speculative"[2] function should be attributed to this muscle; namely the tensing of the cervical fascia to assist prolonged inspiration during forced respiration. The latest edition of *Gray's Anatomy*[2] comments, "so far no useful data in regard to the hyoid musculature as a whole have been contributed by electromyographers" (page 508).

The American opossum (*Didelphis virginiana*), which is regarded as exemplifying both early mammalian cranio–facial organisation in general and the mammalian hyoid apparatus in particular, has been studied by synchronised cinefluorography and electromyography (see legend to Fig. 1).

Jaw movement in the chewing cycle of the opossum is shown in Fig. 1*a*. The associated movements of the hyoid in the antero-posterior plane are also shown (*b*). Movement of the hyoid in both the horizontal and vertical planes is shown in Fig. 1*d*. The chewing cycle begins with the mouth wide open (maximum gape). At this point the hyoid is about a third of the way along its antero-posterior movement path. As the jaw is elevated rapidly, the hyoid moves very slightly upwards but may not significantly change its antero-posterior position. Both the fast closing movement of the jaw and the elevation of the hyoid cease at tooth–food–tooth contact. As the jaw is moved upwards against the resistance of the food in the 'slow close' of the power stroke, high amplitude EMG activity (Fig. 1*c*) is seen in the elevator muscles[12,13]. At the same time, high amplitude activity in the sternohyoid and omohyoid muscles is associated with downwards and backwards movement of the hyoid. No electrical activity was recorded in the anterior suprahyoid muscles during the power stroke. On completion of the power stroke, the jaw has reached its maximum elevation and the hyoid its most inferior and posterior position. The opening stroke of the chewing cycle occurs in two stages; slow opening and then fast opening. In the first, the jaw is moved slowly downwards as the hyoid moves both forwards and upwards. These convergent movements of the jaw and hyoid are associated with activity in the anterior belly of the digastric, the geniohyoid and the genioglossus, all of which are acting to depress the lower jaw and elevate the hyoid simultaneously. There is a small burst of EMG activity in the posterior belly of digastric coincident with the initial early elevation of the hyoid. The sternohyoid and omohyoid are electrically silent during slow jaw opening and do not, therefore, prevent the hyoid from being drawn forwards. Low level activity in the jaw elevators, particularly the masseter and internal pterygoid was recorded during slow opening[12], when the tongue is collecting and repositioning food within the mouth. As the hyoid is moved forwards and upwards, the floor of the mouth and the base of the tongue are also raised by the contracting anterior suprahyoid muscles. The activity in these muscles tends to depress the jaw, which is partially counteracted by the activity in the elevators. Fast opening of the jaw occurs after the hyoid has reached its most anterior and elevated position at the end of slow opening. As the jaw is depressed, the anterior part of the tongue, protruded in slow opening, is retracted sharply. The hyoid is moved slightly upwards and backwards to its midway position. Rapid opening of the jaw is associated with high amplitude EMG activity in all the muscles of the hyoid apparatus.

Contrary to classical anatomical teaching, at no time during the chewing cycle is the hyoid 'fixed'. It shows least movement during the fast close stage of the cycle and most movement during opening. This is not what would be expected were the mandible depressed towards a 'fixed hyoid'. During slow closure in the power stroke, the hyoid moves downwards and backwards; in slow opening it is moved upwards and forwards. There are two important aspects of the pattern of muscle activity responsible for the hyoid cycle. First, the EMG activity in the anterior and posterior bellies of digastric is asynchronous, both in its time of onset and in its peak amplitude; this finding contrasts with the statement "that (in man) the two bellies must contract with equal force"[1]. Both bellies are, however, involved in fast opening when all the muscles of the hyoid apparatus are electrically active and are combining both to depress and retract the hyoid and to depress the lower jaw. Second, during slow opening, the infrahyoid muscles are not actively contracting and do not, therefore, 'stabilise' the hyoid.

In the light of these results, the classical view of the role of the hyoid apparatus must be revised. The hyoid has a cyclical movement completely integrated with that of the jaw and related to the role of the tongue in positioning the food. Further, the hyoid is part of a dynamic and not a basically static system. In man, the acquisition of the upright posture has resulted in some minor shifts in the angulation of the hyoid muscles compared with *Didelphis* but not in any significant change in their anatomy. The initiation and regulation of hyoid movement may, therefore, be seen as the normal function of the omohyoid. This does not, however, preclude the possibility that this muscle, whose anatomy in man has seemed somewhat inexplicable, occasionally assists in tensing the cervical fascia in the specialised respiratory state of prolonged inspiration[1,2].

Fate of teratocarcinoma cells injected into early mouse embryos

ANALYSIS of early mammalian development is complicated by technical difficulties. The initial processes of cellular determination and differentiation in the mouse embryo take place in small populations of cells[1,2], and major embryogenic events occur after uterine implantation when the embryo is largely inaccessible. Recent work, however, suggests that murine teratocarcinomas may provide a convenient model for studying mammalian development[3–6]. These are transplantable tumours of germ cell or embryonic cell origin[3–6], typically consisting of a variety of differentiated tissues and undifferentiated stem cells. The stem cells, called embryonal carcinoma, resemble cells of

§Ref. 20.

early embryos in morphological, biochemical and cell surface properties, and in developmental potential[3–6]. They can be propagated in tissue culture to provide sufficient material for biochemical analysis. After inoculation into histocompatible adult hosts they form differentiated teratocarcinomas. They also differentiate *in vitro*[7,8] where the first stages of their differentiation seem to parallel normal embryonic development. We show here that embryonal carcinoma cells can participate in normal embryogenesis, thus providing further evidence for the validity of the use of these cultures as a model of normal embryonic development.

When mouse blastocysts are injected with genetically distinct embryonic cells[9], they develop normally and tissues of the resulting offspring are often chimaeric, consisting of cells of both donor and host origin. The developmental potential of injected cells can be ascertained from the distribution and genetic activity of their progeny in such chimaeras[10,11]. Brinster[12] injected cells from the ascitic form of an *in vivo* teratocarcinoma into blastocysts of a different genotype and obtained one overtly chimaeric mouse. The purpose of our study was to confirm and extend this work by injecting cells from *in vitro* cultures of embryonal carcinoma into blastocysts. We obtained normal chimaeric mice following injection of two different embryonal carcinoma cell lines. A third line colonised the embryo but the resultant chimaeric mice developed teratocarcinomas postnatally.

Table 2 Rate of development of blastocysts injected with embryonal carcinoma cells after transfer to females that subsequently became pregnant

Cell line injected	Stage of pseudopregnant foster mother	Foetuses recovered / Embryos transferred		Number chimaeric
		9.5 d	Term	
C86	2.5 d	13/18(2)*	—	3(+2?)
SIKR–OSB	2.5 d	—	4/9(1)	1
C17	0.5 d	—	9/13(1)	1
	2.5 d	—	34/58(6)	3
C86	0.5	—	5/12(2)	0
	2.5 d	—	69/93(13)	6

* Figures in parentheses refer to the number of foster mothers to which the embryos were transferred.

The genetic markers used to distinguish embryonal carcinoma cell progeny from the cells of the host embryo were isozymal differences at the glucose phosphate isomerase (GPI) locus (*Gpi-1*), albino or pigmentation, and white-bellied agouti (A^w) or extreme non-agouti (a^e). Details of the origin and characteristics of the cell lines are presented in Table 1. Cultured embryonal carcinoma cells derived from C3H teratocarcinomas were injected into blastocysts obtained by matings of $Gpi\text{-}1^a/Gpi\text{-}1^a$ albino CFLP random-bred mice (Anglia Laboratory Animals Ltd). The 129/Sv–*Sl*–^{i}*CP* derived cell line was injected into $Gpi\text{-}1^b/Gpi\text{-}1^b$ blastocysts obtained from matings of a^e/a^e mice of the AG/Cam-derived balanced lethal yellow (A^y/a^e) inbred line[13].

Clumps of 20 to 40 embryonal carcinoma cells were removed mechanically or with trypsin from the culture vessel, and injected into the blastocoelic cavities of 3.5–4-d blastocysts with the aid of a Leitz micromanipulator assembly[14]. After 1–3 h incubation at 37 °C, blastocysts were transferred either to the uterus of day 3 or to the oviduct of day 0 pseudopregnant females. The foster mothers were either killed on day 10 of gestation or allowed to carry their young to term. Chimaerism in postimplantation embryos and internal tissues of offspring was investigated by electrophoretic analysis of homogenates for GPI in starch gels[15]. External chimaerism in offspring was determined by inspection of the coat and eyes for the presence of pigmented melanocytes or agouti hairs. Material for histological examination was fixed in neutral formal saline, embedded in wax and sections were stained with haemalum and eosin or Masson's trichrome stain.

In a preliminary series of experiments involving C86 cells, the foster mothers were killed on day 10 of gestation and all conceptuses were separated into a trophoblastic and embryonic fraction. Thirteen normal living embryos were recovered, and no resorption sites were present. GPI analysis indicated the presence of a significant minor component of C86 derived isozyme in three conceptuses: in the embryonic portion of one,

the trophoblast of a second, and in both portions of a third. Two other conceptuses showed traces of C86-type isozyme. These results indicated that the injected embryonal carcinoma cells had proliferated in some embryos without obviously interfering with their morphogenesis. In subsequent experiments the embryos were allowed to develop to term.

The rate of development of operated blastocysts (Table 2) compares favourably with that found in previous experiments[14] and argues against embryonal carcinoma cells adversely affecting prenatal development in spite of the relatively large number of cells injected into each blastocyst. Of 121 mice born, 11 contained progeny of the embryonal carcinoma cells (Table 3) and 4 of these were normal healthy animals.

Mouse T120, obtained after injection of SIKR–OSB cells, had small patches of agouti hair in the coat, indicating the presence of embryonal carcinoma derived dermal elements interacting in the normal manner in the hair follicles[16]. This animal was healthy when killed at 6 weeks of age. Analysis indicated extensive chimaerism of internal tissues.

Mice T6, T84, T85, and T89 were obtained after injection of C17 cells. T6, T85 and T89 exhibited pigmentation in both the coat and eyes whereas T84 showed only eye pigmentation. Three remained apparently healthy at 9 weeks of age and the areas of pigmentation have proved stable in relative size and distribution (Fig. 1*a*). Apart from blood, GPI analysis for internal chimaerism of these three animals has not yet been undertaken as they are being test bred. The fourth mouse, T6, developed two subcutaneous tumours postnatally and died at 7 d. GPI analysis demonstrated that embryonal carcinoma-derived cells were present in several macroscopically normal tissues in addition to both tumours.

None of the mice obtained after injection of C86 cells exhibited coat or eye pigmentation; however, six developed one or more tumours which were evident at birth or within 6 d. All except one tumour (in T65) grew rapidly postnatally (Fig. 1*b*), so that all six mice died or were killed during the first 3 weeks of life. All tumours were subcutaneous except one that protruded through the skull from the cerebellar region of the brain and one attached to the liver. The tumours were poorly differentiated teratocarcinomas, consisting chiefly of embryonal carcinoma; GPI analysis indicated the presence of both embryonal carcinoma-derived and host cells. In addition, five of the six animals showed chimaerism of other macroscopically normal tissues, probably indicating the presence of normal, appropriately differentiated cells derived from the embryonal carcinoma. Because of the tumours, however, we cannot eliminate the possibility of numerous small metastases.

Normal embryonic cells can be converted into teratocarcinomas by transplanting embryos of various developmental stages into ectopic sites in syngeneic adult hosts[17–19]. Present experiments suggest that such teratocarcinoma-derived embryonal carcinoma cells taken from culture *in vitro* can participate in normal morphogenesis and differentiation when restored to the environment of the early embryo. We have obtained unequivocal normal chimaeras following the injection of pluripotential cells of two different lines. Embryonal carcinoma progeny in these chimaeras were able to differentiate into apparently normal functional melanocytes of both the coat and iris (T84, T85, T89) and normal dermal elements of hair follicles (T120). In future experiments we intend to use genetic polymorphisms of differentiated functions to investigate whether the embryonal carcinoma progeny in the other chimaeric tissues are functioning like normal differentiated cells of those tissues. Also we are, at present, attempting to increase the level of chimaerism by injecting dissociated cells directly into the inner cell mass of blastocysts to enable more effective interaction between embryonal carcinoma and embryo cells.

All living mice from the present experiments are being test bred to determine whether the embryonal carcinoma cell progeny can colonise the germ line and produce functional gametes. This would raise the possibility of producing mice from a tissue culture cell line selected to carry various mutations and of establishing lines of mice which are models for genetically determined human diseases, or which carry mutant alleles of relevance to studies on development.

We thank Drs S. A. Iles and E. P. Evans for allowing us to enter their data in Table 1; Drs G. R. Martin and C. F. Graham for help and discussions. This work was supported by the

Cancer Research Campaign and the MRC. M.W.McB. was supported by a Canadian MRC Centennial Fellowship.

Note added in proof: Chimaeric mice have been obtained following injection of teratocarcinoma cells from *in vivo* tumours. One chimaera sired 61 offspring, all of which carried genetic markers of the teratocarcinoma cells[21].

Collagen characterisation and cell transformation in human atherosclerosis

COLLAGEN comprises 40–60% of the protein[1,2] and 30% of the weight[3] of human fibrous atherosclerotic plaques. Its deposition in the arterial intima is largely responsible for the occlusive and irreversible nature of coronary and cerebral arterial disease. Four genetically distinct types of collagen have been identified in mammalian tissues and at least five structural genes are involved in their synthesis[4]. The transcription of these various genes seems to be tissue specific. Type I collagen is found in tendon, bone and adult skin, type II is found in cartilage and intervertebral disk, and type IV is restricted to basement membrane. Type III collagen was observed first in newborn human skin[5] and has been isolated and characterised from human aorta and leiomyoma[6]. Initial reports identified both types I and III in human aorta[4,7]. We have now found that fibrous atherosclerotic plaques contain proportions of these two collagens which are different from those occurring in normal arterial wall.

Eight aortas each containing large areas of fibrous atherosclerosis were obtained *post mortem* from middle-aged men (mean age 52 yr), washed free of blood and the adventitia stripped and discarded. Raised white intimal plaques were removed and pooled. Residual segments of aortic media were also pooled. The resulting two fractions were treated separately, but identically, in all subsequent procedures.

Minced, defatted tissues were first decalcified by exhaustive stirring with disodium EDTA. Collagen was then extracted from the washed decalcified samples by stirring for 24 h at 4 °C with 50 volumes of 0.5 M acetic acid containing 200 mg pepsin (Worthington PM, 2,800 U mg^{-1}) per g of lyophilised tissue[8]. Collagen was precipitated from the clarified digest by addition of solid NaCl to a concentraction of 0.9 M, redissolved in 0.5 M acetic acid and dialysed exhaustively against 1.0 M NaCl, 0.05 M Tris, *p*H 7.5. Initial separation of types I and III in each sample was achieved by raising the NaCl concentration in steps of 0.2 M up to 3.0 M. A substantial precipitate of type III collagen was obtained from the aortic medial extract at 1.6 M NaCl, but with atherosclerotic intima the initial precipitate was slight and came down at 1.8 M. At 2.6 M NaCl large amounts of type I collagen were obtained from atherosclerotic intima and smaller amounts from the media.

Samples (20 mg) of each freeze-dried, salt-fractionated precipitate were chromatographed on carboxymethylcellulose (see Fig. 1 for conditions) after denaturation at 45 °C for 40 min. Elution positions of rat skin collagen α1(I), α2 and β12 chains on carboxymethylcellulose are shown in Fig. 1*a*. The 1.6 M NaCl precipitate from aortic media yielded only a trace amount of α1(I). Instead, a broad peak eluted in an intermediate position between β12 and α2 (Fig. 1*a*).

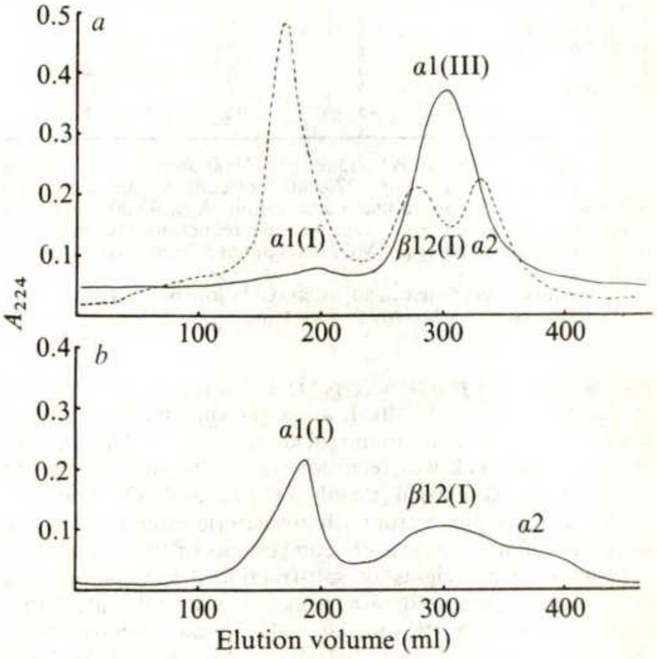

Fig. 1 Carboxymethylcellulose chromatography of aortic collagens on a 16×100 mm column at 40 °C in 0.02 M sodium acetate buffer containing 1 M urea, *p*H 4.8, using a linear gradient of 0.02 M to 0.12 M NaCl over a total volume of 500 ml. *a*, 1.6-M salt fraction from pepsin-treated human aortic media (——) and lathyritic rat skin collagen (– – –). *b*, 2.6-M salt fraction from pepsin-treated human atherosclerotic intima.

The latter component, rechromatographed on an Agarose column previously calibrated with collagen chains and peptides, yielded two major peaks eluting at positions corresponding to V_0 and 270,000 daltons (Fig. 2). Amino acid analysis (given in Table 1) of both major Agarose peaks was identical and seemed very similar to analyses reported for human α1(III)[9]. When the 270,000 molecular weight Agarose peak was reduced and alkylated and rechromatographed, a new component was produced with a molecular weight of approximately 95,000 and an amino acid composition corresponding to that of the original peak (Table 1). This suggested that much of the 270,000-dalton material was in the form $[\alpha1(\text{III})]_3$, held together with interchain disulphide bonds between adjacent cysteine molecules.

Although little collagen was precipitated from medial extracts by 2.6 M NaCl, large amounts were obtained from atherosclerosis intima. The carboxymethylcellulose chrom-

Table 1 Amino acid composition of collagen molecules and chains isolated from human aorta

Amino acid	Media $[\alpha 1(\mathrm{III})]_3$ Ag_1	Media $\alpha 1(\mathrm{III})$ Ag_2	Atherosclerotic intima $\alpha 1(\mathrm{I})$ CMC
3-Hydroxyproline	2	ND	ND

Lysine	28	28	27
Histidine	6	5	3
Arginine	45	46	50

Results are expressed as residues per 1,000 amino acid residues. ND, not determined. Ag_1, 270,000 molecular weight peak from Agarose. V_0 peak had similar composition. Ag_2, 95,000 molecular weight peak obtained from Agarose after reduction, alkylation and rechromatography of Ag_1. CMC, α1(I) derived from carboxymethyl-cellulose.

*Determined as cysteic acid after oxidation by performic acid.

†Determined as carboxymethyl cysteine.

atogram of this fraction (type I) is shown in Fig. 1*b*. The initial peak was identified as α1(I) on the basis of its elution position and amino acid analysis (Table 1). The second broad peak was rechromatographed on Agarose and found to be composed mainly of β12 and α2. Thus the 2.6 M salt precipitate from atherosclerotic intima was found to contain almost exclusively components of type I collagen.

From known weights of salt-fractioned precipitates and areas under chromatogram peaks it was calculated that pepsin-extracted aortic medial collagen was approximately 70% $[\alpha 1(\mathrm{III})]_3$ and 30% $[\alpha 1(\mathrm{I})]_2\alpha 2$. In contrast, collagen extracted from atherosclerotic intima contained only 35% $[\alpha 1(\mathrm{III})]_3$, the remaining 65% of the sample being $[\alpha 1(\mathrm{I})]_2\alpha 2$. Because there was some contamination of intimal samples with underlying media, this value for the percentage of type I in atherosclerotic intima is likely to be an underestimate. The figures also assume that pepsin-solubilised collagen is representative of the whole.

The cells which synthesise these collagens are also different in the two sites. Those of the aortic media are well differentiated smooth muscle cells (SMC) similar to those shown in Fig. 3*a*. Our finding that the collagen of the

Fig. 2 Agarose elution pattern of α1(III) peak from Fig. 1*a*. aortic media is mainly type III, together with previous evidence of type III in leiomyomata[6], suggests that a mixed collagen in which $\alpha 1(\mathrm{III})$ is predominant is a characteristic product of SMC.

It is widely believed that SMC play an important role in atherogenesis[10,11]. There is considerable experimental evidence that many of the cells of the atherosclerotic plaque are derived from medial SMC which have migrated to the intima and proliferated. These cells often lose some of their distinguishing ultrastructural features and have in consequence been named myointimal cells[12] or 'modified' SMC[13]. If type III collagen could be used as a genetic marker of smooth muscle it would provide a functional criterion on which to base the identity of such cells.

In view of the supposed derivation of plaque cells from SMC the finding of large amounts of type I collagen in the intimal plaques was surprising. The pattern of synthesis is more similar to that of adult skin fibroblasts than it is to smooth muscle. Accordingly, we examined the appearance of the thickened aortic intima in the electron microscope. None of the plaque cells resembled SMC. Myofibrils, basement membrane and cytoplasmic dense bodies were absent. Instead, the cells were smaller and their cytoplasm was packed with ribosomes and organelles (see Fig. 3*b* and *c*) and they had the typical appearance of fibroblasts undergoing active protein synthesis[15].

If cells of human fibrous plaques are derived from smooth muscle, it is evident that they have undergone fundamental changes in both morphology and collagen synthesis. Since the new pattern of collagen synthesis would involve change in the rates of translation of genes coding for $\alpha 1(\mathrm{III})$, $\alpha 1(\mathrm{I})$ and $\alpha 2$, we suggest that a basic cell transformation takes place in human atherogenesis. An alternative explanation is that cells of the plaque are derived not from smooth muscle but from fibroblasts resting in normal intima. In that case transformation is unnecessary and it would be best to classify the cells as true fibroblasts. Further study is required to determine which of these interpretations correctly applies to human atherosclerosis.

We thank the Cleveland Clinic, Cleveland, Ohio for autopsy material. The investigation was supported in part by a grant from the US Public Health Service.

Tumour-specific antigen related to rat histocompatibility antigens

ATTENTION has been drawn to the similarities between tumour-associated antigens (TAA) and normal histocompatibility antigens, such as their high degree of polymorphism[1,2], their cell surface behaviour[3], and composition in terms of molecular weight and amino acid composition[4]. These similarities are reflected in methods developed for the isolation of tumour and histocompatibility antigens[5–7]. Furthermore an inverse relationship has been established between the expression of TAA and H-2 antigens on 3-methylcholanthrene-induced murine sarcomas[8,9], whereas the appearance of TAA on aminoazo dye-induced rat hepatomas was associated with deletion of cell surface-expressed normal liver-specific antigens[10].

One interpretation of these findings is that the individually characteristic TAAs on chemically-induced tumours may be modified histocompatibility antigens[11]. This hypothesis has been examined using a tumour-specific antigen preparation isolated from the serum of Wistar rats bearing transplants of a 4-dimethylaminoazobenzene-induced hepatoma (D23). This antigen, purified from immune complexes in tumour-bearer serum by gel filtration in acidic media followed by affinity chromatography on Sepharose 4B-linked syngeneic rat immune IgG, was homogeneous on isoelectric focusing gels in the presence or absence of neutral detergents. It also reacted specifically with antibody in syngeneic hepatoma D23-imune rat serum as shown by immunodiffusion in isoelectric focused gels and its capacity to neutralise membrane immunofluorescence staining of the serum with hepatoma D23 cells (J.G.B. and R.W.B., unpublished).

The highly purified hepatoma D23 antigen was injected intramuscularly in Freund's complete adjuvant into the hind limb of male New Zealand white rabbits, and after three injections at weekly intervals, the rabbit serum was tested by the indirect membrane immunofluorescence test for the presence of antibody directed against the tumour-specific antigen on viable hepatoma D23 cells (Table 1). The fluorescence index was calculated (FI = (% cells unstained with normal rabbit serum − % unstained with test serum)/% unstained with normal rabbit serum). Fluorescence indices of 0.30 or greater were taken to represent significant staining of hepatoma cells by antibody.

Table 1 Fluorescence indices of rabbit anti-D23 purified serum antigen tested against cells from three Wistar tumours

	Fluorescence index against target cells from:		
Serum	Hepatoma D23	Hepatoma D30	Hepatoma D33
Rabbit anti-D23 purified antigen	1.00, 0.97	1.00, 0.95	0.99, 1.00
Rabbit anti-D23 purified antigen absorbed *in vivo**	0.87, 0.79	0.01, 0.10	0.09, 0.07
Rabbit anti-D23 purified antigen absorbed by normal Wistar rat liver membranes†	0.75, 0.83	0.05, 0.03	0.13, 0.12

*Rabbit serum (2 ml) injected intraperitoneally into normal Wistar rats which were bled by cardiac puncture 4 h later.

†Serum (1 ml) absorbed with 50 mg normal Wistar liver membrane protein for 18 h at +4 °C.

The serum from rabbits immunised against the hepatoma D23 purified serum antigen reacted not only against hepatoma D23 cells (FI 1.00–0.97) but also against the two immunologically distinct hepatomas D30 and D33 (FI 0.95–1.00), indicating that this serum recognised antigenic similarities between these three tumours. After absorption *in vivo* or by isolated normal rat liver membranes, the reactivity of the rat antiserum against hepatoma D23 cells was retained (FI 0.75–0.87), whereas that against hepatomas D30 and D33 was lost (FI 0.01–0.13).

Similarly, antisera against the purified hepatoma D23 serum antigen raised in Slonaker rats reacted in a manner similar to the rabbit antiserum (Table 2), so that the unabsorbed antiserum reacted with cell-surface antigens on the three hepatomas used (FI 0.79–0.86). After absorption *in vivo* and *in vitro* with normal Wistar liver membranes, the reactivity against hepatomas D30 and D33 disappeared (FI 0.11–0.20), but that against hepatoma D23 was retained (FI 0.42–0.55).

Table 2 Fluorescence indices of Slonaker anti-D23 purified serum antigen tested against cells from three Wistar tumours

Serum*	Fluorescence index against target cells from: Hepatoma D23	Hepatoma D30	Hepatoma D33
Slonaker anti-D23 purified antigen	0.83, 0.82	0.79, 0.85	0.86, 0.80
Slonaker anti-D23 purified antigen absorbed *in vivo*	0.40, 0.42	0.18, 0.20	0.15, 0.17
Slonaker anti-D23 purified antigen absorbed by normal Wistar rat liver membranes	0.45, 0.55	0.17, 0.11	0.19, 0.20

*Absorption conditions as for Table 1.

The antigen used to immunise rabbits and Slonaker rats was highly purified and homogeneous by all the techniques used (J.G.B. and R.W.B., unpublished). Thus, unless the tumour-specific antigen comprised only a small portion of the immunising material and large amounts of histocompatibility antigens were also present, one must suggest that the hepatoma D23 antigen is a modified histocompatibility antigen.

This hypothesis was examined further by labelling the purified hepatoma D23 antigen with ^{125}I (ref. 12) and examining the binding of this labelled antigen to columns of various immunoabsorbants. Four immunoabsorbants were prepared by coupling to CNBr-activated Sepharose respectively, Slonaker antinormal Wistar liver antiserum, normal Slonaker serum, Wistar antihepatoma D30 antiserum and Wistar antihepatoma D23 antiserum. Each gel (5 ml packed volume in PBS) was packed into large Pasteur pipettes containing a plug of glass fibre to prevent loss of gel beads. ^{125}I-labelled D23 antigen (10 ng in 20 μl PBS) was allowed to run on to each column and the sample was washed in to the column with 0.5 ml PBS. Flow was stopped and the columns incubated at room temperature for 3 h, at which time 10 ml PBS were washed through the column at 0.5 ml min^{-1} and fractions collected. Any bound material was eluted with 3-MCF$_3$COONa *p*H 7.3 and the eluate dialysed against PBS. Both unbound and eluted material were concentrated to 0.5 ml and tested to see if binding to CNBr-Sepharose-linked Wistar antihepatoma D23 antiserum occurred (Table 3).

Of label added to the Slonaker antinormal Wistar liver immunoadsorbent, 75.4% could be bound and eluted and 81.5% of this could be rebound and eluted from Wistar antihepatoma D23. This parallels the results obtained with an initial column of Wistar antihepatoma D23 in that 77.6% of material could be bound and eluted and 87.5% of this could be rebound to a similar column. Conversely, with material added to normal Slonaker or Wistar anti-D30 immunoadsorbants, very little was bound and eluted (29.7 and 25.2% respectively) and this material would not rebind to Wistar antihepatoma D23 (17.5 and 0.7%). Material not bound to these columns (65.4 and 71.6% label), however, would bind to the Wistar antihepatoma D23 (89.5 and 85.75% respectively). Thus the purified hepatoma D23 antigen shows points of identity with antigens recognised by Slonaker rats on normal Wistar liver membranes.

Table 3 Binding of ^{125}I-labelled hepatoma D23 antigen to various immunoabsorbents

Immunoabsorbant	% ^{125}I-labelled hepatoma D23 antigen Unbound	Bound and eluted
Slonaker antinormal Wistar liver	19.5	75.4
Normal Slonaker serum	65.4	29.7
Wistar antihepatoma D30	71.6	25.2
Wistar antihepatoma D23	19.0	77.6
Material unbound on columns of*		
Slonaker antinormal Wistar liver	74.7	20.5
Normal Slonaker	5.4	89.5
Wistar antihepatoma D30	10.8	85.75
Wistar antihepatoma D23	80.0	16.3
Material eluted from column of*		
Slonaker antinormal Wistar liver	15.2	81.5
Normal Slonaker	79.6	17.5
Wistar antihepatoma D30	95.0	0.7
Wistar antihepatoma D23	10.8	87.5

*This material was tested for binding to CNBr-Sepharose-linked Wistar antihepatoma D23.

In this rat hepatoma D23 system, Baldwin and Glaves[10] have shown that when tumour antigens are present there is a deletion of normal antigens recognised by a xenogeneic antiserum. Furthermore, Invernizzi and Parmiani[11] have shown that the tumour-associated transplantation antigens of chemically-induced mouse sarcomas crossreacted with allogeneic histocompatibility antigens. They concluded that in this system the tumour antigen was the result of carcinogen-induced mutation at the level of histocompatibility genes, as there seemed to be a linkage between the tumour antigen and the H-2 system. The work reported here confirms and supports the work of Invernizzi and Parmiani[11] and shows that the tumour-associated transplantation antigen of a chemically induced tumour is a modified histocompatibility antigen.

Lethality of interferon preparations for newborn mice

WE have previously reported that the daily subcutaneous inoculation of newborn mice with mouse brain interferon preparations was not accompanied by any discernible effect on their growth or development[1]. Far more potent interferon preparations have been shown to inhibit cell division in normal adult mice. Thus, the multiplication of allogeneic spleen and syngeneic bone marrow cells was inhibited when injected into X-irradiated adult mice treated for several days with potent interferon preparations[2], and liver regeneration was inhibited in partially hepatectomised adult mice treated with interferon[3]. We report here that daily injection of potent interferon preparations results in the death of newborn mice. To our knowledge this is the first report of untoward effects associated with interferon treatment of the normal animal. These results may be relevant to the use of interferon in man.

Newborn Swiss or C3H mice from pathogen-free colonies were injected subcutaneously in the interscapular region with the different preparations. They received daily inoculations of 0.05 ml for 1 week beginning on the day of birth and 0.10 ml daily thereafter for 1 month. In all experiments there were at least two litters of mice per group. In some experiments different treatments were undertaken on

‡Mean day of death ± s.d.

§Titre of the Sendai virus-induced L cell interferon was 1 : 240,000.

‖Inactivated by heating at 60 °C for 1 h; residual titre 1 : 100,000.

¶Inactivated by treatment with 0.02 M sodium periodate at pH 4 for 3 h at 4 °C; residual titre 1 : 600.

**Titre of human leukocyte interferon was 1 : 2,000,000 (MRC reference interferon (69/19) units) as assayed on human diploid fibroblasts.

NT, Not tested.

Mouse interferon from suspension cultures of C243 cells[4] induced with Newcastle Disease Virus (NDV) was concentrated and semipurified as described previously[5]. Mock interferon was prepared in a manner identical to that used in the preparation of interferon with the exception that the interferon inducer, NDV, was either omitted altogether, or added for 1 h immediately before collecting the culture supernatant (experiment 4). For experiment 7, mouse interferon prepared in monolayer cultures of L cells inoculated with Sendai virus, was concentrated by selective precipitation with ammonium sulphate as described for the C243 cell interferon[5]. All interferon and control preparations were further dialysed for 24 h at 4 °C against 0.01 M perchloric acid before testing for toxicity on a line of L1210 cells resistant to interferon[6].

Specific activity of mouse C243 cell interferon preparations was in the range 0.7–3×10^6 units per mg protein and that of the L cell interferon was 2×10^4 units per mg protein. C243 cell control preparations contained approximately the same amount of protein per ml as the C243 cell interferon (that is, 1.5–3.4 mg ml^{-1}). Partially purified human interferon prepared in leukocyte suspensions inoculated with Sendai virus was generously provided by Dr K. Cantell[7]. Specific activity was 3.5×10^5 units per mg protein. Interferon units quoted are as measured in our laboratory and one of our units equals 4 mouse interferon reference units.

labelled mice within the same litter. All mice were weighed daily. On occasions moribund mice were killed for histological examination of their organs. Some mice in the different groups surviving at 1 month were killed, others were observed for 3–6 months.

Newborn mice inoculated with interferon (titre 1:800,000) seemed to develop and grow normally for the first 6–7 d. In the ensuing few days an increasing difference in weight was observed between interferon-treated mice and their control littermates. Interferon-treated mice died between day 8 and 14. The lethality of mouse interferon preparations for newborn mice is illustrated in Table 1 and the salient points may be summarised as follows: All (122 out of 122) newborn Swiss and C3H mice inoculated daily with C243 cell interferon preparations (titre 1 : 800,000 died. Six out of seven newborn Swiss mice inoculated with another type of mouse interferon preparation (titre 1:240,000), derived from L cells (and induced with a different virus), also died. No deaths were observed in mice inoculated daily with control preparations (0 out of 82); with inactivated mouse interferon preparations (0 out of 30); with human leukocyte interferon preparations (0 out of 23) or left uninoculated (0 out of 178).

To determine the minimal lethal amount of interferon, newborn Swiss mice were inoculated daily with tenfold dilutions of an interferon preparation (titre 1:800,000). Only mice inoculated with the undiluted interferon preparation died, whereas those inoculated with preparations of titre 1 : 80,000 or less seemed to grow normally; and no abnormalities were observed on histological examination of their organs at 1 month. These findings are in accord with our previous results[1] indicating that newborn mice inoculated with mouse brain interferon preparations (titre 1 : 8,000–1 : 16,000) developed and grew normally without presenting any abnormalities on histological examination. In experiment 5 (Table 1) mouse interferon was only partially inactivated by heating and the residual titre was found to be 1:100,000. Mice treated with these preparations seemed to develop normally. Thus, our results suggest that daily inoculation of newborn mice with interferon preparations of titre 1 : 100,000–1 : 240,000 (experiment 7, Table 1) would prove fatal for 50% of the mice.

The most striking abnormality on killing moribund interferon (both C243 and L cell interferon) treated mice was a pale grey liver. Examination of the liver of these mice under the light microscope revealed large areas of cell degeneration and necrosis without any inflammatory reaction (Fig. 1*c* and *d*). Examination of liver sections under the electron microscope showed an accumulation of fat, decreased glycogen, swelling of both the mitochondria and the rough endoplasmic reticulum, and discrete nuclear and nucleolar abnormalities. No viral particles were observed. The only other abnormalities on light microscopic examination were: some diminution of the cortical region of the thymus in some mice (and presence of some pycnotic cells in the cortex) and poorly differentiated germinal follicles in the spleens of most mice.

In the experiments described, interferon treatment of newborn mice proved lethal when begun on the day of birth and continued daily. When, however, treatment was initiated on day 6 of life and continued daily for 14 d, mice seemed to grow normally and no mortality was observed. Two mice were killed on day 21 and histological examination of their livers revealed an increased granularity of the cytoplasm without cellular degeneration. The resistance of these mice may be related to the stage of differentiation of the liver at the time interferon inoculations were begun.

We have no reason to believe that the interferon preparations exerted a nonspecific toxic effect, or that an infectious agent was responsible for the hepatic lesions observed in interferon-treated mice. The results of pertinent experiments may be summarised as follows: First, all interferon and control preparations were incubated (1 : 10 final dilution, that is, 80,000 interferon units) with interferon-resistant L1210 cells[6]. Neither the multiplication nor the viability of these cells was affected over a 48-h period. Representative interferon preparations exerted no detectable toxic effect on confluent monolayer cultures of mouse L or chick embryo cells. Second, one litter of 10 newborn Swiss mice was inoculated intracerebrally daily for 3 d with a C243 cell interferon (titre 1:800,000). All mice survived. No toxic effects were noted and no abnormalities were observed over a 3-month period. Third, two moribund interferon-treated mice with gross liver abnormalities (confirmed

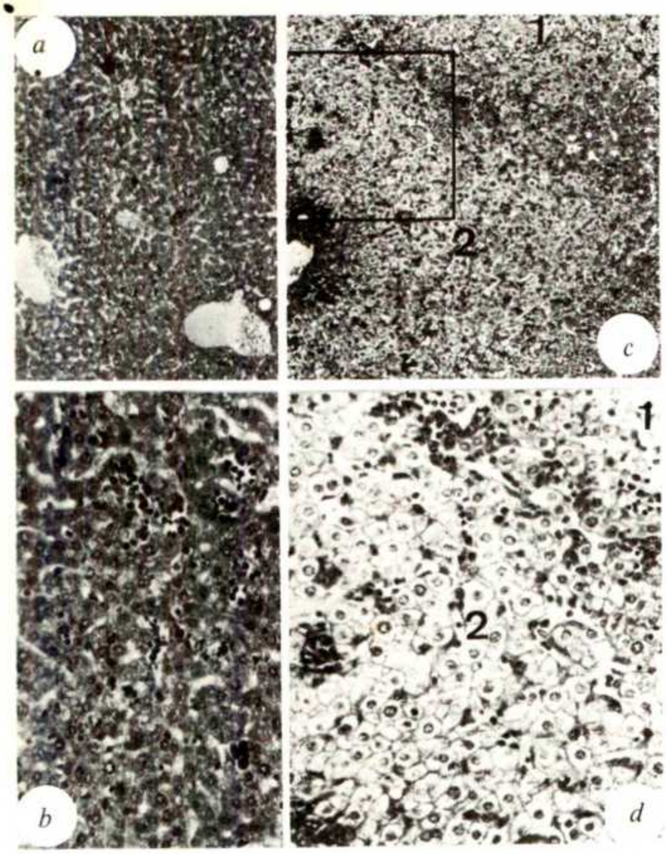

Fig. 1 Sections of liver of 10-d-old Swiss mice. *a* and *b*, Untreated (× 75.6 and × 189); *c* and *d*, treated with a C243 interferon preparation (titre 1:800,000; × 75.6 and × 189) showing focal area of necrosis (1) and diffuse cellular degeneration (2).

on light and electron microscopic examination) were killed and extracts of liver and kidney were inoculated subcutaneously into newborn mice and into primary cultures of newborn mouse kidney. No abnormalities were observed in newborn mice kept for 3 months. No cytopathic agent was detected in cell culture. Using immunofluorescent techniques, inoculated cell cultures did not seem to contain either lymphocytic choriomeningitis or murine hepatitis viral antigens.

Our results show therefore that daily inoculation of newborn mice with potent interferon preparations is lethal and that mice die with extensive liver damage. Our findings may be relevant to the treatment of patients with exogenous interferon. If we suppose that a newborn baby is as sensitive to human interferon preparations as a newborn mouse is to mouse interferon, then our results suggest that the daily inoculation of 50 ml human interferon preparation (titre 1 : 800,000) might represent a lethal dose for a 3-kg baby (that is, compared with 0.05 ml for a 3-g mouse). Our results also raise the possibility that lower doses of interferon may cause adverse effects in newborn infants that are not immediately apparent. We are aware of the hazard of this analogy, but patients are currently being treated with potent interferon preparations and it is therefore incumbent on clinicians to be aware of the potential dangers of interferon therapy at least in infants. On the other hand it is also important to emphasise that adult patients have been treated twice or three times weekly for extended periods of time with potent leukocyte interferon preparations without showing any untoward effects[8,9].

We thank Ms J. Begon-Lours, J. Buywid, and M. T. Bandu for assistance; Dr C. Huet and Professor W. Bernhard for the electron microscopic examination of liver; and Dr J. C. Guillon for his attempts to isolate infectious agents from the liver. M.G.T. thanks the Philippe Foundation. This work was supported in part by INSERM, CNRS and the Fondation pour la Récherche Médicale.

Effect of cortisol, prolactin and ADH on the amniotic membrane

VERY little is known about the endocrine regulation of amniotic fluid volume and composition[1,2]. Vizsolyi and Perks[2] have described a technique for studying the transfer of fluid across the amniotic membrane of the guinea pig *in vitro*. They showed that arginine vasotocin and arginine vasopressin (antidiuretic hormone, ADH) could stimulate the movement of fluid from the maternal to the foetal side of the membrane. Because prolactin is found in remarkably high concentrations (up to 10 µg ml^{-1}) in primate amniotic fluid[3,4] and affects renal function[5–8], we have investigated the effect of prolactin as well as of arginine vasopressin on the guinea pig amniotic membrane. Because cortisol can reverse the usual antidiuretic effect of ADH and because prolactin can restore this effect[9], we have also investigated the action of cortisol. We have shown that ADH and prolactin have opposite effects on the amniotic membrane and that, in both cases, their actions can be reversed by cortisol. We suggest that fluid transfer across the amniotic membrane may provide an insight to the functioning of the kidneys, the ciliary body and the choroid plexus.

The apparatus used was similar to that described by Vizsolyi and Perks[2]. Female guinea pigs were killed in the last three weeks of pregnancy. Two portions of the amniotic membrane were tied over the ends of two glass tubes, each with an end area of 1 cm^2; the foetal surfaces of the membrane faced into the tubes. The tubes were filled to a depth of 10 cm with 'amniotic' saline (Fig. 1) and suspended in oxygenated baths of 'maternal' saline with the fluid level in the tubes 2 cm above that in the bath. The tubes did not float, but were supported by balanced levers connected to rods passing through Sangamo Weston displacement transducers. Changes in weight of the tubes resulting from fluid movements produced movements of the levers and changes in transducer output which were continuously recorded using Devices equipment. The system was calibrated by adding known volumes of fluid to the tubes. Both the relative osmolarities and the 2-cm H_2O pressure head favoured movements of fluid from the tube ('foetal' side) to the bath ('maternal' side). Eight animals were used in preliminary experiments in which various hormone concentrations were tested. Two sets of six experiments were then carried out as indicated in Table 1; in each experiment, the *A* and *B* membranes came from the same animal. The results are shown in Figs 1 and 2. All hormones were added to the foetal side of the membrane.

In the control period no significant movement of fluid

Table 1 Experimental addition of hormones to the foetal side of the amniotic membrane *in vitro*

Experiment	Periods* 1	2	3	4
1*A*	Control	Prolactin (200 ng ml^{-1})	Prolactin (1,000 ng ml^{-1})	Prolactin (1,000 ng ml^{-1})+ cortisol (200 ng ml^{-1})
1*B*	Control	ADH (0.05 IU ml^{-1})	ADH (0.1 IU ml^{-1})	ADH (0.1 IU ml^{-1})+ cortisol (200 ng ml^{-1})
2*A*	Control	Cortisol (200 ng ml^{-1})	Cortisol+ADH (0.05 IU ml^{-1})	
2*B*	Control	Cortisol (200 ng ml^{-1})	Cortisol+prolactin (1,000 ng ml^{-1})	

* Each period lasted for 30 min.

occurred in either direction Prolactin at 200 ng ml^{-1} caused a transfer of fluid to the maternal side; 1,000 ng ml^{-1} caused a further movement in the same direction. The addition of cortisol (200 ng ml^{-1}) to the prolactin completely reversed the direction of fluid movement The opposite was found with ADH (0.05 and 0.1 IU ml^{-1}); it caused a movement to the foetal side which was reversed by cortisol. In the second series of experiments, cortisol added alone caused a fluid movement to the maternal side. ADH then caused a further movement in the same direction but prolactin had the reverse effect, moving fluid to the foetal side.

With respect to the amniotic fluid, the prolactin was used in concentrations which are, in primates at least, physiological[3] whereas the other two hormones were probably at concentrations much greater than those found in amniotic fluid[2,10]. We therefore suggest that the effect of prolactin alone is likely to be the one which is of practical importance If prolactin does cause a movement of fluid out of the amniotic sac this could account for the hydramnios which is frequently found when human amniotic fluid prolactin concentrations are low[3].

It is already known that prolactin, cortisol and ADH can interact in the formation of urine[7-9] and of aqueous humour[11]. Cortisol and prolactin have been shown to have opposite effects on some fish bladders[12,13]. Because of its relative simplicity, the guinea pig amniotic membrane may provide a good mammalian model for our understanding of amniotic fluid regulation and as an indication as to what may be happening at other sites where urine, aqueous humour, cerebrospinal fluid and gastrointestinal secretions are formed.

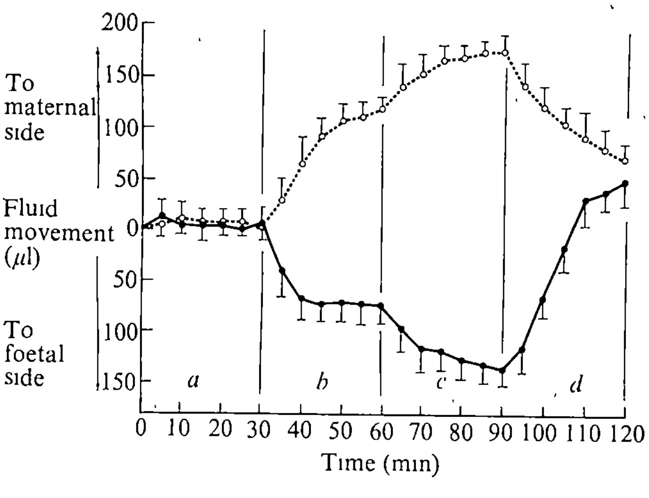

Fig. 1 The fluid movements during the various incubation periods in experiments 1*A* and 1*B* (Table 1) At each point the net amount of fluid which has moved since time zero is indicated. Each figure represents the mean of six experiments and the bars indicate the s.e.m The 'amniotic' saline had the following composition: sodium 125.0, potassium 6 2, calcium 4.5 and magnesium 2.3 mM l^{-1}, all added as chloride· 1 0 g l^{-1} glucose: 10 ml phosphate buffer at *p*H 7.8 was added per litre, giving a final *p*H of 7.4 and osmolarity of 286 mosmol l^{-1}. The 'maternal' saline was made up as follows: sodium 150.0, potassium, 5.5, calcium 4 4, magnesium 2.6 mM l^{-1}, all added as for the amniotic saline giving a final *p*H of 7.4 and osmolarity of 314 mosmol l^{-1} The maternal saline was bubbled continuously with oxygen and maintained at 37 °C. Vizsolyi and Perks[2] studied the compositions of guinea pig amniotic fluid and maternal plasma and devised the 'amniotic' and 'maternal' salines to reproduce the natural fluids as closely as possible *a*, Control; *b*, prolactin (200 ng ml^{-1}), ADH, 0 05 IU ml^{-1}; *c*, prolactin (1,000 ng ml^{-1}), ADH, (0 1 IU ml^{-1}); *d*, prolactin (1,000 ng ml^{-1}) plus cortisol (200 ng ml^{-1}), ADH, (0.1 IU ml^{-1}) plus cortisol (200 ng ml^{-1}) ○, Prolactin; ●, ADH.

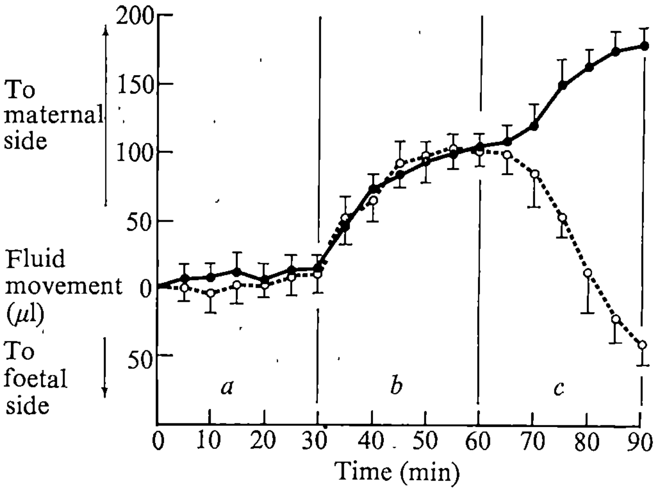

Fig. 2 The fluid movements during the various incubation periods in experiments 2*A* and 2*B*. *a*, Control; *b*, cortisol (200 ng ml^{-1}); *c*, cortisol (200 ng ml^{-1}) plus ADH (0.05 IU ml^{-1}) or prolactin (1,000 ng ml^{-1}). Each point represents the mean of six experiments and the bars indicate s.e.m. ●, ADH, ○, Prolactin.

Action of progesterone on preoptic thermosensitive neurones

FEMALE body temperature rises by about 0.5 °C at or near ovulation and remains elevated during the luteal phase of the menstrual cycle. Sustained elevation of basal body temperature is observed also during early pregnancy. These effects have been attributed to progesterone, but little is known about the mechanisms involved[1]. We have now found that the hormone affects the activity of the thermosensitive neurones in the preoptic area of the brain.

These neurones change their discharge frequency in response to changes in local brain temperature: that of warm-sensitive neurones increases with a rise in temperature[2–3], while that of cold-sensitive neurones increases with a fall in temperature[4]. Intravenous pyrogen in anaesthetised animals (cat and rabbit) decreases the activity of warm-sensitive neurones and increases that of cold-sensitive neurones[5–8].

Our investigation followed preliminary studies of 23 unanaesthetised female rabbits, injected intravenously with progesterone (more than 5 mg kg^{-1}). There was a rise in rectal temperature of 0.6 °C, with the highest elevation in core temperature 2 h after injection. Progesterone was dissolved in propylene glycol, but the solvent alone did not cause temperature to rise. We have therefore investigated the effect of systemic administration of progesterone on the thermosensitive neurones.

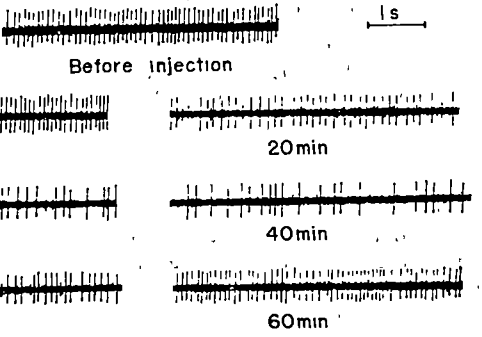

Fig. 1 Discharges of the preoptic warm-sensitive neurone in response to intravenous administration of progesterone in the female rabbit.

Thirty-four female rabbits (2.5–4.0 kg) were anaesthetised with urethane (1 g kg^{-1}), tracheotomised and mounted on a stereotaxic apparatus. (Details of the method have been described before[3].) A thermode was implanted in the preoptic area, 1.5 mm lateral to the midline, and brain temperature was measured by a thermocouple placed in the frontal plane, 3.0 mm from the thermode. Impulses of single neurones were recorded on tape and impulses per second were counted with a data processing computer. A small amount of iron was then deposited electrolytically at the tip of the electrode for histological localisation. A neurone with a regular rate of firing was identified as warm-sensitive, cold-sensitive or temperature-insensitive by its responses to local warming and cooling. The effect of progesterone was observed on twenty warm-sensitive, seven cold-sensitive and five insensitive neurones. Progesterone was dissolved in 50% propylene glycol (5 mg ml^{-1}). When the thermal response of a neurone had been observed, the brain temperature was kept at 37.5 °C and progesterone (10 mg in 2 ml) was injected intravenously. In a typical warm-sensitive neurone (Fig. 1), the average rate of firing before injection was 11.2 impulses s^{-1}. After a latency of about 20 min, this decreased to 7.7 at 24 min, to 6.6 at 40 min and returned to 10.0 at 60 min. Of the 20 warm-sensitive neurones tested, 15 decreased their firing rate by 38–70% after administration of progesterone. The thermal responses of these 15 neurones had not changed when observed 60 min after administration, with the exception of one neurone which showed a decreased thermosensitivity. The rate of firing of five warm-sensitive neurones was unchanged for 2 h after intramuscular administration of progesterone.

In seven cold-sensitive neurones the rate of firing increased after administration of progesterone given intramuscularly in three cases and intravenously in the other two. In one of these neurones, the rate of firing increased from 6.4 to 12.0 impulses s^{-1} 6 min after injection. Five thermally-insensitive neurones were not affected by progesterone and two warm-sensitive neurones were not affected by propylene glycol.

Plasma concentration of progesterone rises quickly after intravenous administration and returns to a control level in about 1 h (refs 9 and 10). This may explain the short duration of action of progesterone that we observed. We do not know whether the thermosensitive neurones tested in this study are true thermoreceptors or interneurones transmitting temperature signals in a complex neural network of temperature regulation. Nor are we certain whether the neuronal effects which we observed were caused by progesterone *per se* or by its metabolites. Furthermore, the quantitative relationship between oestrogen and progesterone in the luteal phase is complex and oestrogenic hormones are known to cause a slight decrease in body temperature[11–12].

It seems likely, however, that the decreased activity of warm-sensitive neurones and the increased activity of cold-sensitive neurones in the preoptic area result in an upward shift of the 'set point' of body temperature, as with the effects of pyrogen. The rise of basal body temperature in the luteal phase seems to be related, at least in part, to the direct or indirect action of progesterone on preoptic thermosensitive neurones.

Excitation of phasically firing supraoptic neurones during vasopressin release

THE neurohypophysial hormones vasopressin and oxytocin are synthesised within separate neurones of the hypothalamic supraoptic and paraventricular nuclei[1] and each hormone can be liberated independently. Haemorrhage[2] and bilateral

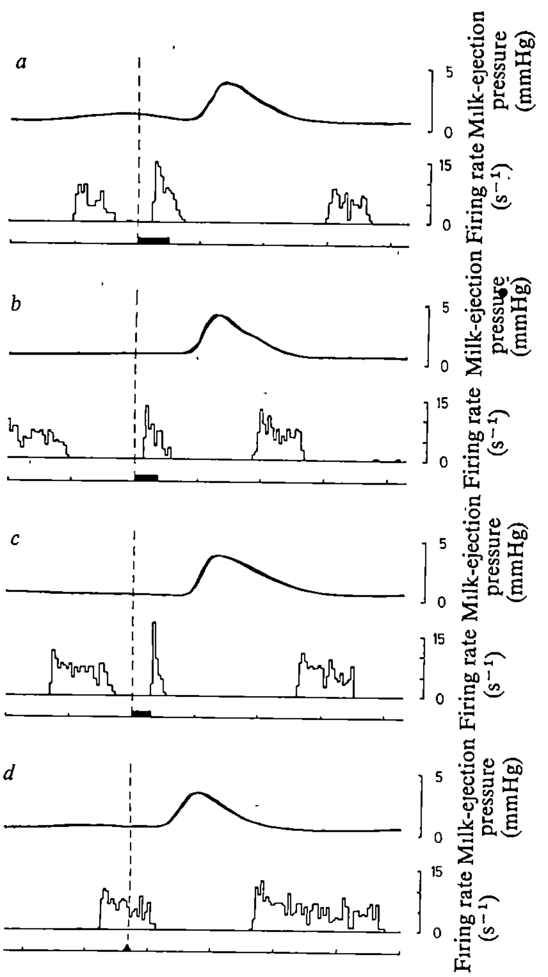

Fig. 1 Responses of a phasically active supraoptic neurone and of intramammary pressure to bilateral carotid occlusion. Antidromically identified neurone fired with bursts of activity separated by silent intervals. Bilateral occlusion of the common carotid arteries (black bars) for 15 s (*a*), 11 s (*b*) and 9 s (*c*) evoked a short supplementary burst of activity from the neurone 4–9 s after the onset of occlusion (dashed line). In two instances (*a* and *c*) the peak firing of the evoked burst exceeded that of the spontaneously occurring bursts. The rise in intramammary pressure occurred 18–20 s after the onset of each occlusion, and was of similar amplitude and duration to that occurring 16 s after the intravenous injection of 250 μU arginine vasopressin in the black triangle in (*d*). Time base, 30 s.

carotid occlusion[3] release vasopressin without oxytocin, whereas oxytocin is released without vasopressin during suckling[4,5] and parturition[6]. The neuroendocrine cells produce all-or-none action potentials which propagate to the neural lobe, where they trigger hormone secretion[7]. Action potential firing of individual endocrine cells falls into two principal categories: most fire continuously and randomly at 1–2 spikes s^{-1}, while the rest have a phasic pattern of firing, periods of bursting activity alternating every 10–60 s with periods of silence[8].

Lincoln and Wakerley[9] recorded the firing rates of supraoptic neurones in rats during suckling, and found that the reflex excited predominantly the randomly firing neurones. We have therefore investigated supraoptic neuronal activity during stimulation which is known to release only vasopressin. We found that, during bilateral occlusion of the common carotid arteries, supraoptic neurones are excited and that this activation is confined almost exclusively to phasically active neurones.

We used lactating female rats under urethane anaesthesia (1.2 mg kg^{-1}). Their common carotid arteries were occluded by a clamp which exerted no tension. Blood pressure and intramammary pressure were measured routinely. The brain was exposed from the ventral surface and supraoptic neurones were identified by antidromic invasion after electrical stimulation of the pituitary stalk[10].

Of 101 cells studied, 60 had a random pattern of firing, 33 had a phasic pattern and 8 were silent. Bilateral occlusion of the common carotid arteries reproducibly excited 30 of the phasically firing neurones. Occlusion of the arteries during the silent period of a cycle was followed by a burst of action potentials which started less than 10 s after the onset of occlusion. If applied during a spontaneous burst, occlusion often prolonged that burst. Random neurones responded to occlusion in a much more varied manner: 4 were excited, 14 showed slight excitation followed by prolonged inhibition, 24 showed inhibition alone and 18 were unaffected. Of the silent cells, 4 were excited.

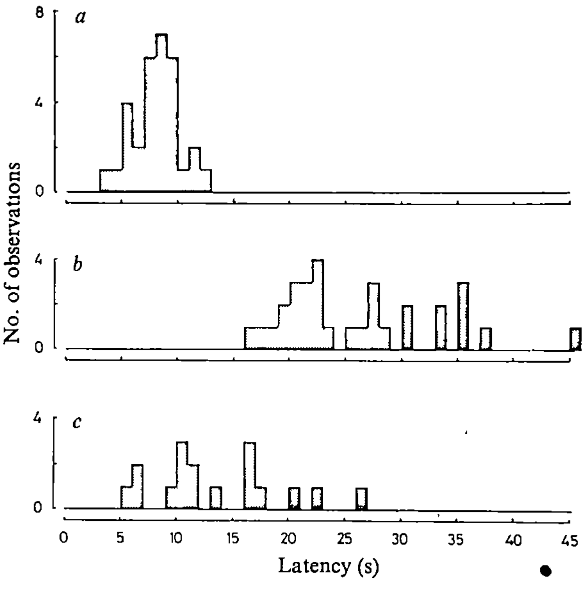
The response of a phasic neurone in a lactating rat to carotid occlusions of various duration is illustrated in Fig. 1. The neurone responded to periods of occlusion of 15, 11 and 9 s with a burst of activity starting 4–9 s after the onset of occlusion.

In Fig. 1*a* and *c* the evoked bursts had a higher peak rate than the spontaneous bursts. Approximately 20 s after the onset of neuronal firing, intramammary pressure increased, showing that one or both neurohypophysial hormones had been released. The increase in pressure was approximately equivalent to that which followed the injection of 250 μU arginine vasopressin into a jugular vein. In this neurone the duration of the evoked burst seemed to be controlled by the duration of the occlusion; this was also seen in some other neurones.

Recording of intramammary pressure in lactating rats takes advantage of the fact that vasopressin causes milk ejection even though its activity is only about 20% of that shown by oxytocin. If the milk-ejection response to carotid occlusion was caused by hormone released as a result of activation of supraoptic neurones, the response should begin approximately one circulation time after the onset of the evoked burst of activity. This occurred regularly, as shown in Fig. 2

The mean latency of the milk-ejection response was 26.2 s. This must be explained by the delay before the cells are activated and the time taken by the hormone to reach the mammary

Fig. 2 Histogram of the latencies of neuronal and milk-ejection response to bilateral carotid occlusion and to exogenous vasopressin. Results from eight supraoptic neurones, *a*, Latencies between the beginning of occlusion and the onset of the stimulus-evoked burst of action potentials ranged between 3 and 13 s, with mean latency (±s.e.) of 8.1±0.4 s (n = 31). *b*, Latencies between the beginning of the same occlusions as in *a* and the onset of the stimulus-evoked milk-ejection response. Mean latency (±s.e.) was 26.2±1.3 s (n = 31). *c*, Latencies between the injection into the jugular vein of 0.25–1.0 mU vasopressin and the onset of the ensuing milk-ejection responses. Mean (±s.e.), 13.7±1.4 s (n = 17).



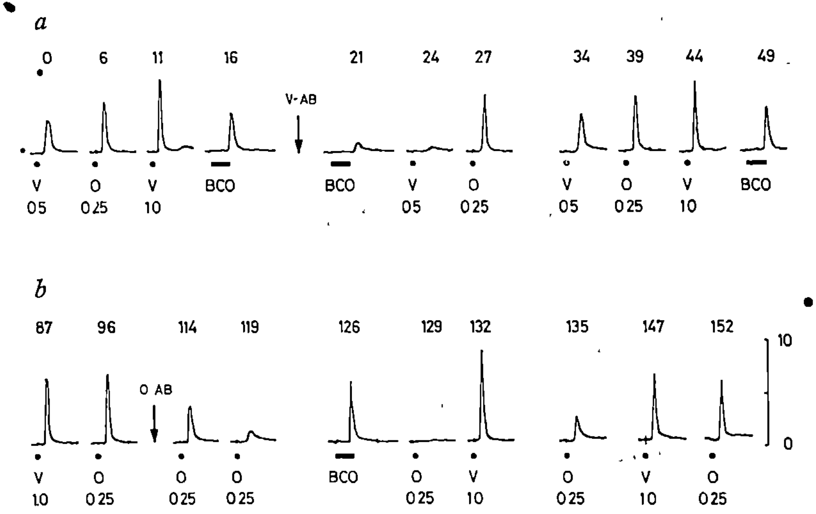


Fig. 3 Effects of injected antibodies to vasopressin and oxytocin on milk-ejection responses to bilateral carotid occlusion and to exogenous neurohormones. Records show milk-ejection responses after exogenous vasopressin (V), exogenous oxytocin (O) and 30 s bilateral carotid occlusion (BCO) before and after intravenous injection into the jugular vein of antibodies at the arrows. Numbers beneath records give concentrations of hormones in mU. Vertical scale is in mmHg. Figures above the responses indicate time (min) after the start of the experiment. Injections or occlusions were made at approximately 5-min intervals, except immediately after antibody injection. The responses are consecutive, but the record is not continuous. *a*, Effect of vasopressin antibodies (V-AB). BCO caused milk-ejection responses equivalent to 0.5 mU vasopressin and slightly less than 0.25 mU oxytocin. After injection of antibodies, responses to BCO and vasopressin are almost abolished whereas response to oxytocin is unaffected. *b*, Effect of oxytocin antibodies (O-AB). Injection of antibodies at arrow progressively abolishes response to 0.25 mU oxytocin without reducing responses to either BCO or vasopressin. Note reversibility of the effects of both antibodies.

gland after release. The observed latency of the onset of the cell response was 8.1 s, and the observed latency of milk ejection following injection of vasopressin into a jugular vein was 13.7 s. The difference between the observed latency of the milk-ejection response to occlusion and the sum of the latter two figures is because the cells do not reach their peak firing rate immediately and because injections into the jugular vein underestimate the time taken by hormone to reach the mammary gland from the pituitary.

There is evidence that carotid occlusion liberates only vasopressin in cat and dog[11], but there is no published evidence that this is so in rats. Since both neurohypophysial hormones increase intramammary pressure, it was necessary to establish that the responses we observed were due to vasopressin and not to oxytocin. We used two approaches. First, rats anaesthetised by methane were subjected to a 60-s occlusion and then decapitated. The extracted trunk plasma[12] was assayed by radioimmunoassay for vasopressin and oxytocin[13] and compared with that of extracts from rats subjected to the same surgery but omitting carotid occlusion. The results showed that occlusion increased mean (±s.e.) plasma vasopressin from 303 ± 70 to 970 ± 199 pg ml^{-1} ($n = 8$; t test, $P < 0.01$) but the increase in oxytocin was much smaller and not significant ($P > 0.1$). Second, intrajugular injections of the anti-vasopressin and the anti-oxytocin antibodies were given to lactating rats in conjunction with bilateral carotid occlusion. Results from one animal are shown in Fig. 3. Injection of 0.2 ml of undiluted rabbit plasma containing the specific anti-vasopressin antibody[13] depressed the milk-ejection responses to carotid occlusion and to intravenously injected arginine-vasopressin, without affecting that to exogenous oxytocin. Conversely the oxytocin antibody abolished the response to oxytocin but to neither occlusion nor vasopressin.

Occlusions of 5–10 min duration cause vasopressin secretion in cats and dogs, and following section of the sinus nerves, hormone secretion is abolished, indicating that the response is mediated neurally[11]. Our results indicate that in the rat occlusion of much shorter duration is a stimulus for vasopressin secretion and excites nearly all phasically firing supraoptic neurones; most randomly firing cells are either inhibited or unaffected.

These observations complement the report that, during naturally occurring milk ejection in rats, about half of the randomly firing supraoptic neurones were powerfully excited, whereas phasic neurones were not involved[9]. These findings suggested that randomly firing neurones are those that secrete oxytocin. Since the excitatory input to the supraoptic nuclei in response to bilateral carotid occlusion is apparently channelled almost exclusively to the phasically active neurones, these cells might represent a distinctive class of vasopressin-secreting neurones.

Activity of phasic neurosecretory cells during haemorrhage

Approximately 25% of the neurones projecting to the neurohypophysis from the paraventricular (PV) and supraoptic (SO) nuclei of the hypothalamus fire phasically and such a pattern is seldom seen in other hypothalamic cells[1]. Phasic neurones respond to osmotic stimuli[2] but are rarely activated by suckling[1,3]. It is tempting therefore, to associate these cells with the secretion of vasopressin rather than oxytocin. The functional relationship of their phasic pattern to hormone release, however, remains obscure. We have studied phasic PV neurones during haemorrhage, which releases vasopressin, sometimes with small amounts of oxytocin[4]. Haemorrhage evoked changes in phasic units over a period long enough for a detailed analysis of their behaviour. Our results show the importance of pattern

Table 1 Changes in the activity quotient and intraburst frequency of phasic neurosecretory cells during blood removal and blood replacement

	Control values	Change during blood removal				Change during blood replacement

‡ Many of the cells were quiescent during blood replacement and this precluded a statistical analysis of the changes in intraburst frequency during this period.

modulation in phasic neurones and suggest that the mechanism for vasopressin release differs from that described for oxytocin release during suckling[1,3].

Lactating female rats (300–350 g), anaesthetised with urethane (1.1 g kg^{-1}), were prepared for intramammary pressure recording[1]. Cannulae were introduced into the saphenous artery for monitoring blood pressure and into the right atrium through the jugular vein to remove blood. Animals were then placed in a stereotaxic frame and antidromically identified units were recorded in the PV nucleus by techniques described previously[1,3]. After locating a phasic unit, we recorded 10–15 min of baseline activity before examining the effect of a 4-ml haemorrhage over a period of 4 min (1.3 ml per 100 g body weight; 15% of blood volume). The first and last 0.5 ml of blood collected were used for plasma osmotic pressure determination and vasopressin assay. Two minutes after haemorrhage, the blood was returned over 4–6 min. The volume of blood taken for assay was replaced with warm isotonic saline. Where possible, the test was repeated for each cell 20–30 min later. Samples were centrifuged and the plasma stored frozen at −20 °C until assay. The blood cells were washed in saline and reinjected in a minimum volume of isotonic saline before a further unit was tested.

Vasopressin could not be detected in all samples after haemorrhage, probably because of the relative insensitivity of the assay (rat antidiuretic assay: minimum detectable level > 32 μU per ml plasma). In a series of tests, however, the plasma content of antidiuretic activity after blood removal (median 56 μU ml^{-1}, $n=21$) was significantly higher ($P < 0.001$, Mann–Whitney U test) than control levels (median < 32 μU ml^{-1}, $n=32$). The median value for plasma oxytocin was < 25 μU ml^{-1} both before ($n=23$) and after ($n=17$) haemorrhage, but in two tests oxytocin release was detected. Blood pressure usually dropped from about 100 mmHg to 30–40 mmHg during blood withdrawal and returned to normal levels after blood replacement (Fig. 1). Plasma osmotic pressure (range 295–315 mosmol kg^{-1}) did not change.

Sixty-nine antidromically identified PV units were encountered, of which 15 (22%) fired in a phasic pattern. At histological examination, all were shown to be located in the PV nucleus. The mean duration of the bursts varied considerably between cells (range 6.9–48.6 s) as did the duration of the silent periods (range 9.9–22.2 s); however, for individual neurones the periodicity was quite regular. Ten of the phasic units were recorded throughout the full haemorrhage test. For each minute of the different periods (control, blood out and blood back) the following parameters of spike activity were measured: (1) The activity quotient, Q, which is the total duration of the bursts (s) in 1 min divided by 60; (2) the intraburst frequency, f, representing the mean firing rate within the bursts; and (3) the overall frequency, F, which is the total number of spikes in 1 min divided by 60.

During haemorrhage, the most consistent effect was a prolongation of the bursts (Fig. 1) resulting in a significant increase in Q during each of the first 4 min (Table 1). In

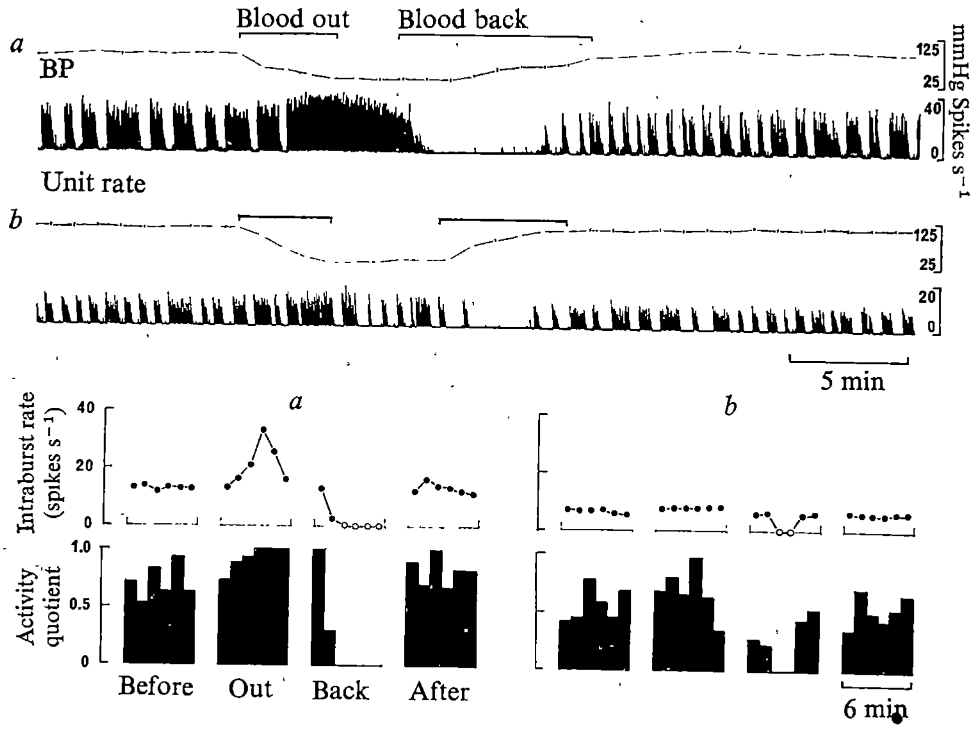

Fig. 1 Records of the firing pattern of 2 phasic cells (a and b) to show the changes which occurred during the withdrawal and replacement of 4 ml blood. Blood pressure decreased rapidly during blood withdrawal and returned to control level soon after blood replacement. Beneath the records are plotted the changes in firing rate within the bursts (f) and the proportion of time for which the cells were firing (activity quotient, Q). Haemorrhage increased Q for each of the cells tested and one of the cells showed an increase in f. In contrast, blood replacement decreased the values of both Q and f. ○, Period during which the cells were totally inactive.

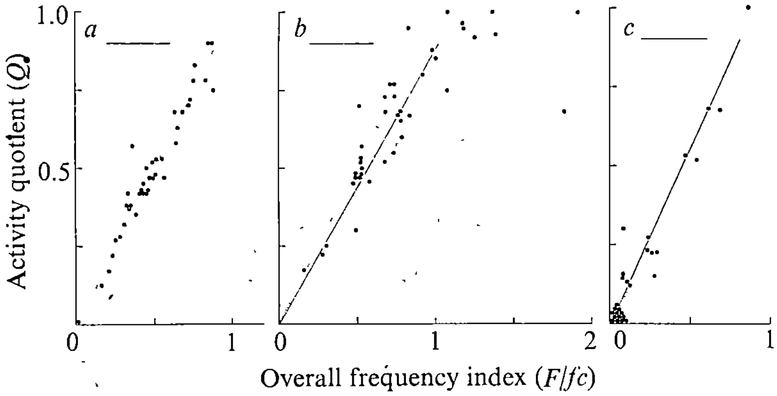

Fig. 2 The relationship between activity quotient (Q) frequency within the bursts (f) and overall frequency (F) during the control period (*a*), blood withdrawal (*b*), and blood replacement (*c*). Q, f and F have been established for each response and they are related by the equations $F = Qf$ or $Q = F/f$. So that the results of all the tests could be considered as a whole, we used the expression F/fc where fc is the mean frequency within the bursts during the control period. If the intraburst frequency remains constant (that is, equal to fc), Q and F/fc are related linearly and all the points fall on the line defined by $Q = F/fc$. If f increases the points fall on the right of the line; if f decreases the points fall on the left of the line. Regression lines have been calculated for the three experimental conditions. For values of Q between 0 and 0.90, the correlation coefficients are highly significant (respectively $r = 0.97$, $r = 0.68$, $r = 0.97$ and $P < 0.001$) and the regression coefficients of the three lines are not significantly different ($P < 0.3$ variance ratio test and Student's t test). $F/fc = 1.01Q - 0.01$ (*a*); $1.06Q + 0.07$ (*b*); $0.9Q + 0.01$ (*c*)

extreme cases, this remained at unity for several minutes (cell *a*, Fig. 1). Intraburst frequency (f) also changed but less consistently and later: the mean increase was significant during the third and fourth minutes. These events resulted in an increased mean overall frequency (F) from a control level of 3.93 spikes s^{-1} to 9.60 spikes s^{-1} in the fourth minute of haemorrhage. Blood replacement produced opposite effects, with reduction in Q resulting from shortened bursts. Many neurones became silent, but occasionally when bursts did occur f decreased. During the third minute F fell to 0.1 spikes s^{-1}. Recovery occurred within a few minutes of the end of the test. In neurones tested twice, the second response was similar to the first.

The relative importance of the change in burst duration and in intraburst frequency is shown in Fig 2, which correlates Q with a measure of the change in overall frequency, F/fc. For Q up to 0.90 the correlation is highly significant during control period (Fig 2*a*), blood removal (Fig. 2*b*) and blood replacement (Fig. 2*c*). Furthermore, the slopes of the three regression lines, which provide a measure of the average intraburst frequency, did not differ significantly in the experimental situations. Thus, f did not change appreciably until Q approached unity, that is, when the cell tended to fire continuously.

These changes within individual cells may explain the observations of Arnauld *et al.*[5] in the SO nucleus of the dehydrated monkey: as plasma osmotic pressure increased the predominant types of cells were first slow-firing cells, then phasic cells and finally fast, continuously-firing cells. We may conclude that the phasic pattern is a functional state of activity of a cell which at other times can be silent or firing continually. The significance of this phasic state is possibly that phasic cells are synchronised to produce an episodic discharge of neurohypophysial hormone. In normal conditions there is no obvious synchronisation of bursts[6] but overlapping activity within a population of neurones inevitably increases as the duration of bursts increases. The modulation of burst duration, which in our experiments preceded changes in intraburst frequency could provide a precise mechanism for regulating hormone release. An increase of intraburst frequency would further augment hormone release[7].

These observations do not prove that phasic cells secrete vasopressin, nevertheless we now know that they are activated by hyperosmotic injections[2], dehydration[5], carotid occlusion[8] and haemorrhage, all of which cause vasopressin release, and that they do not seem to be involved in oxytocin release[1,3]. We propose, therefore, that, on the basis of their neurophysiological performance, PV and SO neurones projecting to the neurohypophysis may be separated into oxytocinergic cells—characterised by their high frequency synchronous discharge during suckling[1,3]—and vasopressinergic cells—characterised by a tendency to fire asynchronously in phases, the duration and frequency of which determine the rate of vasopressin release.

Induction of photoreceptor voltage noise in the dark in *Drosophila* mutant

RANDOMLY occurring, discrete voltage fluctuations (quantum bumps) have been recorded in photoreceptors of several arthropods[1-4]. It is thought that these bumps sum to produce the receptor potential[5,6]. We have investigated the relationship between photoexcitation of the visual pigment and the production of quantum bumps using a mutant of *Drosophila melanogaster*—a third chromosome recessive mutant described by Cosens and Manning[7], in which the electroretinogram decays to baseline during a strong, prolonged stimulus. We will call this mutant the transient receptor potential mutant (*trp*).

Experiments consisted of intracellular recordings from the photoreceptors of intact preparations of white-eyed *trp* mutant (*w*; *trp*). Figure 1*a* shows intracellularly recorded responses of a single photoreceptor to various intensities of green light ($\lambda = 540$ nm). Figure 1*b* shows a plot of the intensity–response relationship for the initial transient, and the subsequent steady-state phase of the responses.

In normal flies the steady state persists for the entire duration of the stimulus. The mutant response to dim light is similar to that of the wild type (Fig. 1*a*, bottom). With increased stimulus intensities, however, the mutant response has a large initial amplitude (as in the wild type), but it decays during stimulus to the same low, steady-state level observed with dim stimuli. The rate of the decay and the final steady-state level attained, vary among individual flies—the response often decaying to the dark-resting potential level.

In the *trp* mutant, voltage noise can be seen superimposed on the response at all the stimulus intensities tested (Fig. 1*a*). The noise level during the steady-state phase of the mutant response is greater than the dark noise level, and it shows little change in amplitude with increases in stimulus intensity. In contrast, in the wild type, the voltage noise amplitude greatly decreases with increased stimulus intensity. The fact that the voltage noise of relatively large amplitude is detected in the mutant response at all intensities rendered the *trp* mutant particularly useful for the present investigation.

The two upper traces of Fig. 2 are intracellular responses to weak, and to 100 times more intense light. The two lower traces are magnifications (×3) of the portions of the two upper traces indicated by vertical bars. The figure shows that the response to the weak light consists of slow potential-fluctuations (noise). Similar noise was recorded and analysed in wild-type *Drosophila*,[6] where the noise seemed to come from quantum bumps occurring at a low rate. The similarity of the noise recorded here, suggests that the mutant noise also arises from quantum bumps. The mutant response to stronger light (first and third traces), after decaying nearly to the steady-state level (Fig. 2), also displays voltage fluctuations, similar to the bump noise seen in the responses to weak light (second and fourth traces). Since bumps are expected to have their maximum amplitude when elicited from a dark-adapted photoreceptor using dim stimuli, the above result suggests that the bumps elicited in the mutants by strong light also have the same maximum amplitude after the receptor potential has decayed to nearly the steady-state level. It follows, therefore, that the decay of the mutant response during stimulus arises not from the decrease in the bump size, but from a decrease in the number of bumps composing the response.

Figure 1 shows that the steady-state amplitude saturates at a relatively low stimulus level. The saturation of the steady-state amplitude is accompanied by saturation of the response noise characteristics (Fig. 3*a*). This was demonstrated by calculating the autocovariance $C(\tau)$ (Fig. 3*a*) from the noise superimposed on the steady-state phases of the responses shown in Fig. 1, using the formula:

$$C(\tau) = \overline{[v(t) - \overline{v(t)}]\,[v(t+\tau) - \overline{v(t)}]} \qquad (1)$$

where v is the amplitude of the receptor potential in the steady-state phase, t is the time at which v was measured, and τ is the time lag. The first point, ($\tau = 0$) in the curves is the variance, a measure of noise amplitude. Once the stimulus is strong enough to be above the saturation intensity for the steady-state phase, the autocovariance shows little dependence on stimulus intensity (Fig. 3*a*). The autocovariance, calculated from the steady-state response of the same cell at even higher intensities than those shown in Fig. 3*a*, also showed little dependence on light intensity. Since the steady-state responses to stimuli of very different intensities have nearly the same amplitude (Fig. 1, log $I = -2.5$ and -1.5) and noise characteristics, that is, nearly the same variance and autocovariance (Fig. 3*a*), shot-noise analysis[5] suggests that these responses are produced by superposition of nearly the same number of quantum bumps having similar average bump amplitudes.

In *Drosophila*[8,9], as well as in other invertebrates[10–14], an intense coloured stimulus that shifts a substantial amount of the visual pigment (rhodopsin) to its thermally stable state (metarhodopsin), induces an excitatory process manifested by a prolonged depolarising afterpotential (PDA), which far outlasts the stimulus. Photoconverting the pigment back from metarhodopsin to rhodopsin induces an inhibitory process, and depresses or prevents the PDA from occurring. Induction and depression of the PDA in the *trp* mutant are shown in Fig. 3*b*. The blue light, which shifts rhodopsin to metarhodopsin, depolarises the cell, and the depolarisation is accompanied by an increase in the noise level of the response. When the blue light is switched off, the cell remains depolarised (PDA), and the noise level remains increased during the entire PDA period. The red stimulus shifts the pigment back from metarhodopsin to rhodopsin, depresses the PDA (when the light is switched off), and reduces the noise level to the level before PDA induction. Figure 3*a* shows the autocovariance calculated from the noise recorded in the dark, during PDA, from the same cell analysed in Fig. 1 and 3*a*. The similarity between the curves calculated from the light-coincident noise and the PDA noise, suggests that the PDA noise also arises from bumps.

The decay of the receptor potential is possibly caused by light adaptation. Light adaptation has been found to reduce the amplitude of bumps[5]. Figure 2 shows, however, that the bump amplitude does not decrease, while the mutant receptor potential amplitude does decrease, during illumination with stronger stimuli. Furthermore, the application of the shot-noise analysis suggests that, at the saturated steady-state level, the responses to both weaker and stronger stimuli consist of bumps of approximately the same number and amplitude. Both these

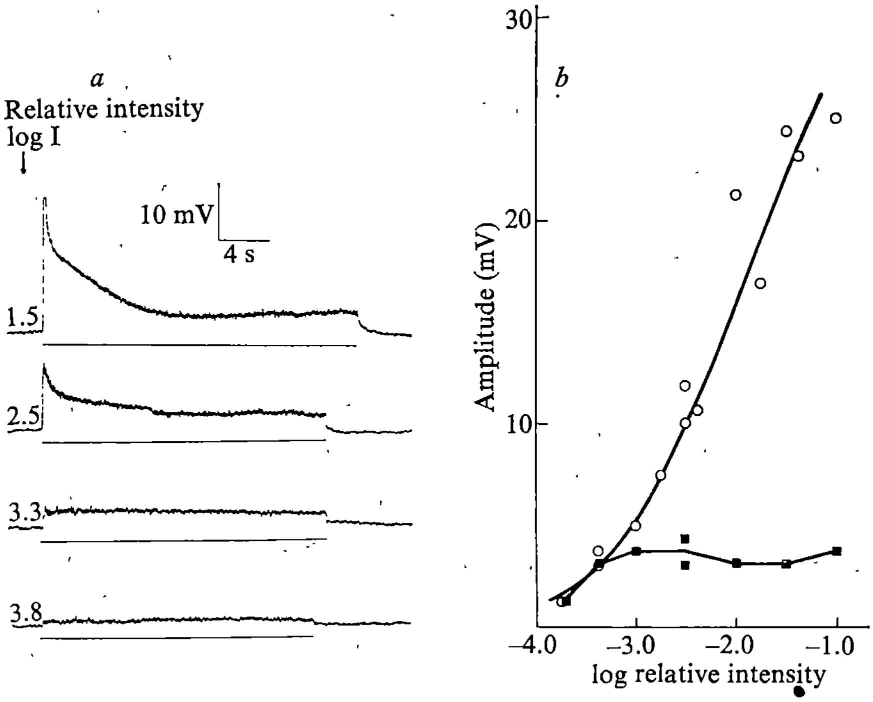

Fig. 1 *a*, Intracellularly recorded responses from photoreceptors of the white-eyed *trp* mutant to various intensities of monochromatic 540-nm green light (half peak bandwidth of 16 nm). The light source was a Xenon arc lamp used in conjunction with Bausch and Lomb high-intensity monochromator. The unattenuated illuminance was 3.0 $\times 10^{14}$ photons cm^{-2} s^{-1} at 480 nm, 3.3$\times 10^{14}$ photons cm^{-2} s^{-1} at 520 nm, and 3.6$\times 10^{14}$ photons cm^{-2} s^{-1} at 540 nm. The lines below the responses indicate the duration of the light stimulus. *b*, A plot of the amplitude–log intensity curves for the transient phase (○) and the steady-state phase (■) of the response. All data points were measured from the cell whose responses are presented in Fig. 1*a*.

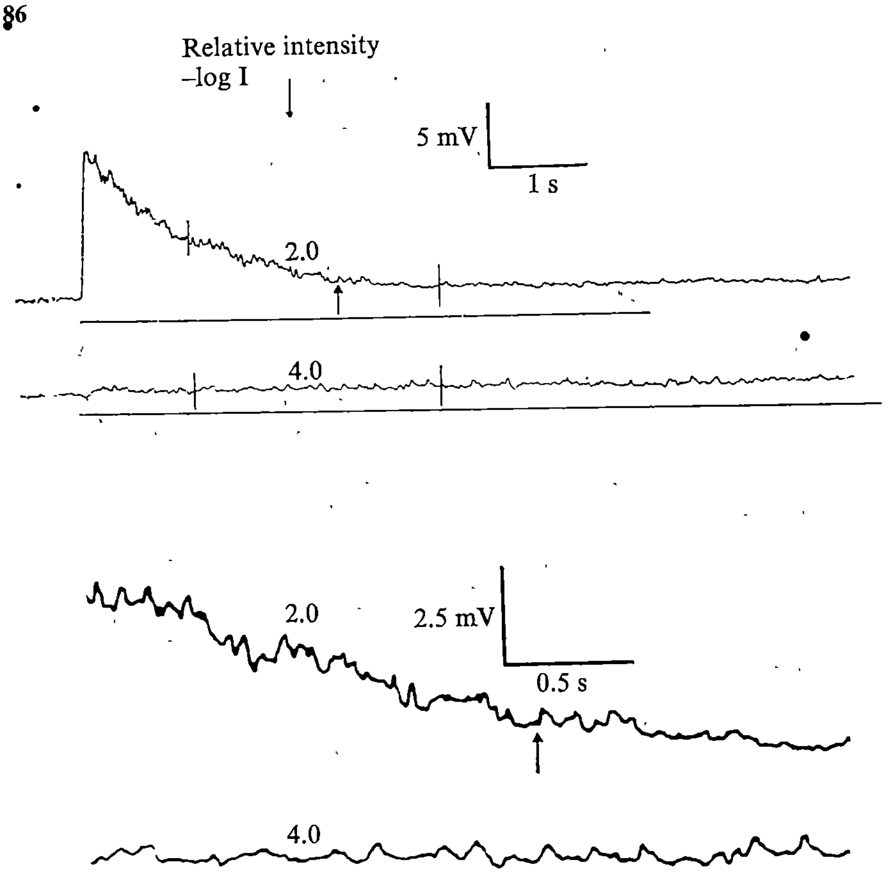

Fig. 2 Intracellularly recorded responses from a single photoreceptor of *trp* to the monochromatic 520-nm green light attenuated by 2.0 (first trace) and 4.0 (second trace) neutral density filters. The two lower traces are ×3 magnifications of the marked portions of the two upper traces. The responses were filtered with a high frequency cutoff filter (half power cutoff at 40 Hz), to facilitate observation of bumps. The arrows indicate the approximate time after which, the response to the stronger light shows noise characteristics similar to the response to the weaker light.

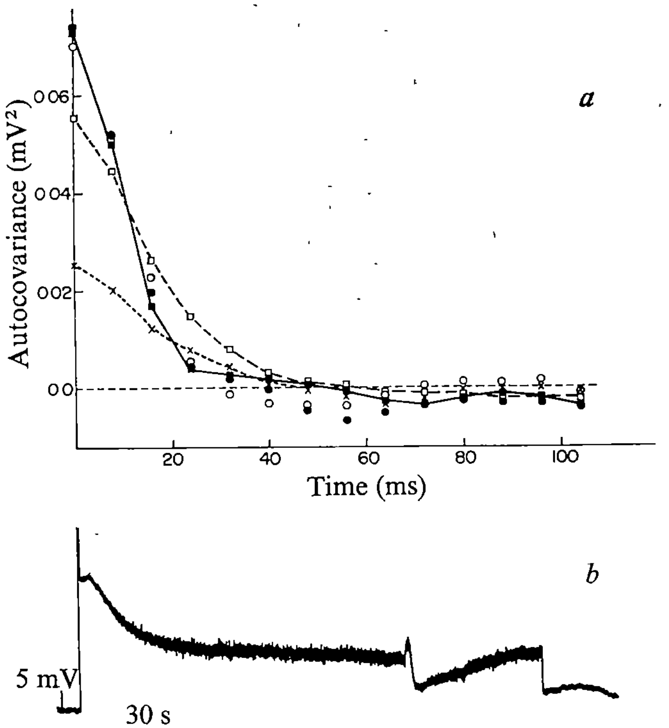

Fig 3 *a*, Autocovariance functions calculated from dark noise (×), the steady-state responses (□, −log I = 3.8; ■, −log I = 2.5; ○, −log I = 1.5) shown in Fig. 1 and the PDA recorded from the same cell (●). The calculations were done from 750 points sampled at 8-ms intervals The ordinate is the autocovariance $C(\tau)$ in mV² and the abscissa is the time lag τ in ms. The responses were filtered with a high frequency cutoff filter (half power cutoff at 30 Hz) before the analysis. Calculation without filtering gave similar results. *b*, An intracellularly recorded PDA response from the photoreceptor of the mutant *trp*, induced by blue and depressed by red stimuli The stimuli originated from a quartz iodide lamp filtered through Baird Atomic B3 interference filters, having transmission peaks at 480 nm and 600 nm. Illuminances were 4.0×10^{16} photons cm^{-2} s^{-1} and 2.5×10^{16} photons cm^{-2} s^{-1} for the blue and red stimuli, respectively.

results make the light adaptation hypothesis improbable. Another possible explanation is that the decay of the receptor potential occurs in the mutant *trp*, because the stimulus bleaches a substantial fraction of visual pigment, and the pigment does not regenerate normally. This explanation, too, is unlikely because the decay of the potential to the steady-state level occurs at intensities that activate less than 1–3% of the visual pigment, when measured spectrophotometrically or by using a response similar to the early receptor potential[15]. We therefore suggest, on the basis of the results shown in Fig. 2, that the decay of the receptor potential during a stimulus arises from a reduction in the quantum efficiency of bump production. The fact that individual bumps in the mutant appear to be normal, although their number is reduced, suggests that the mutation affects an intermediate step of phototransduction, and the fact that PDA induction in the *trp* mutant is accompanied by the induction of bump noise after the cessation of stimulus, suggests that the coupling between the photoexcitation of the visual pigment and the production of the bump is not direct, and that the PDA and the stimulus-coincident response share some common pathway.

We thank Dr S. E. Ostroy and Mrs Meegan Wilson for making the spectrophotometric measurements and Drs S. R. Grabowski and S. Nakajima for critical reading of the manuscript. This work was supported by grants from NSF and the NIH.

Possible contribution of ionic clustering to molecular packing of collagen

An analysis of the primary structure of the α1 chain of a collagen demonstrated that electrostatic and hydrophobic interactions between collagen molecules were maximal when the rod-like molecules were staggered by 234*n* amino acid residues, where *n* is 0, 1, 2, 3 or 4 (ref. 1). It was not possible, however, to determine what value of *n* was most likely. This information would help to select from among possible molecular packing models[2,3]. Doyle *et al.*[4] re-examined the electrostatic interactions in an attempt to determine *n*. Since amino acid side chains of opposite charge frequently occur close to each other in the sequence[1], they considered that these potential intrachain ion pairs might function as dipoles with approximately the same direction in the molecule as in the sequence. If antiparallel dipoles on adjacent molecules were attractive (Fig. 1*a*) and parallel dipoles were repulsive, they found that the net number of attractions was maximal at $n = 1$ and negative at other values of *n*. They concluded that dipole–dipole interactions were important in stabilising the native fibril and that the Smith microfibril[5] was favoured over other packing models since it is essentially a helix of collagen molecules staggered by 234 residues between nearest neighbours.

Although we find the assumptions made by Doyle *et al.*[4] difficult to accept, they were apparently able to discriminate from among possible values of *n*. This suggests that the reason should be more carefully examined. We discuss here other aspects that may be important and propose as an alternative concept that ionic clustering may contribute significantly to the stabilisation of collagen fibril structure.

First, interactions between dipoles cannot be estimated when the location of the charges is not well defined. This point is of particular importance in the case of collagen. The charges are at the ends of side chains, which may assume many configurations, and there are generally three sets of charges at any level since there are three similar or identical chains in the molecule. Therefore, neighbouring charges of opposite sign in a single chain will not necessarily form a dipole in an actual structure, and even if dipoles are formed, the contributing ions and their orientation would be difficult to predict. A related conclusion is that the ions would be able to arrange themselves so as to minimise electrostatic repulsion, which then would not be a major factor, contrary to the assumption of Doyle *et al.*[4].

Second, there is information in the sequence, not explicitly used by Doyle *et al.*[4], that explains their result without recourse to a consideration of dipole–dipole interactions. Not only are amino acid side chains of opposite charge found close to each other in the sequence much more often than would occur by chance, but glutamic acid and arginine are not equally distributed between position X and Y in the collagen triplet Gly–X–Y, with the result that about three out of four positive charges precede glycine and about three out of four negative charges follow glycine in the sequence. Therefore triplets of the form Y–Gly–X and Gly–X–Y, where Y has a positively charged side chain and X has a negatively charged side chain, are common. Of the fifty 'dipoles' considered by Doyle *et al.*[4], fifteen are of the former type and thirteen are of the latter type. This geometry suggests an arrangement (Fig. 1*b*) of four alternating unit charges approximately in a line that could result in cooperative electrostatic interactions with a lower potential energy than two separated ion pairs and a more favourable stereochemical relationship than the two 'dipoles' in Fig. 1*a*. An examination of molecular models shows that such an arrangement is possible because of the separation of the one pair by a glycine residue. Furthermore, the arrangement provides a reason for the unusual distribution of glutamic acid and arginine. Similar arrangements of other opposing antiparallel charge pairs can be devised. This approach to the location of ionic groups leads to the conclusion reached by Doyle *et al.*[4] that $n = 1$, if the same scoring system is used. If, however, the possibility of repulsive interactions is de-emphasised and other arrangements of charges are allowed, as we argue, a most probable value of *n* can no longer be selected with confidence by this analysis.

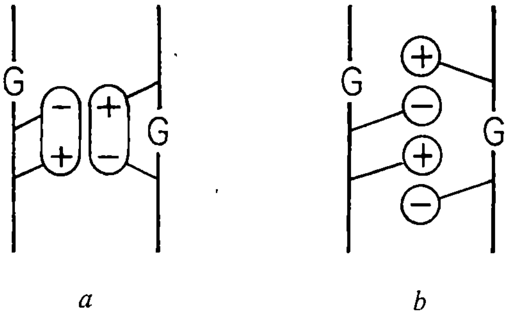

Fig. 1 *a*, Antiparallel dipoles between collagen molecules considered to be attractive by Doyle *et al.*[4]. *b*, An alternative arrangement of the ions to form a line of alternating charges. G is glycine. The positive and negative ions show two characteristic orders of charged amino acids in the triplet sequence of collagen chains.

The considerations discussed here suggest a concept that may help in understanding how collagen fibrils are stabilised. The argument is as follows. Since the collagen molecule has three similar or identical chains as already noted, and since more than one chain per molecule may contribute groups to interacting edges between molecules, an arrangement of the type shown in Fig. 1*b*, if viewed in three dimensions, could involve additional ionic groups. Furthermore, there are often more than two ionic groups near each other in the sequence, and it is possible that an interesting region may involve more than two molecules. Therefore, clusters of ions may exist. Schematic representations of the Smith microfibril suggest that as many as 16–20 ions could cluster in ordered arrangement. These would be expected to approximate the properties of an ionic crystal and contribute some measure of stability to the collagen fibril structure analagous to crystal field energy. This could be an especially important contribution if the clusters were in the interior of the Smith microfibril, or one of the similar alternative structures, since the movement of water, other small molecules, and amino acid side chains would be restricted, increasing the likelihood of cooperative ordering and depolarisation. A more complete analysis may settle some of the details of the molecular packing of collagen, such as the value of *n*, but this has not yet been done.

The principle of ordered ionic clustering proposed here may apply generally to supramolecular structures, which create extended regions where movement is restricted. Guss *et al.*[6] have found an example by X-ray diffraction of a helical form of hyaluronic acid which has a line of alternating charges of opposite sign down the centre of the helix.

Mobile charge carriers in photosynthesis

CURRENT mechanistic models of energy transduction in photosynthesis, envision that the energy of the photons collected by the bulk antenna chlorophyll, is funnelled to special sites called reaction centres, where the primary charge separation events occur[1]. If the primary oxidant and reductant are separated physically by only a few, or few tens of angstroms, changes in the dielectric properties should become evident[2]. Several laboratories have sought such evidence with equivocal results[3-6], although one group, using methods similar to ours, has reported qualitative, positive results[7].

We report here direct confirmation of the presence and trapping of charge carriers of both signs, their mobilities and relative quantum yields, and an estimate of the distance between the separated units of charge.

Our experiments measured the light-induced changes in the real and imaginary parts of the complex dielectric constant, $\varepsilon = \varepsilon' + i\varepsilon''$, of photosynthetic samples at the microwave frequency 9 GHz. Changes in the imaginary part of the dielectric constant, ε'', reflect the losses or photoconductivity, $\Delta\sigma$, whereas changes in the real part, ε', can be related to light-induced changes in the polarisability, α, from which a distance can be estimated[8-10]. The signs and Hall mobilities of the carriers were determined by measurements of the light-induced Faraday rotation. The apparatus consisted of a phase coherent microwave instrument including a bimodal cylindrical transmission cavity[11], the design and performance of an earlier version have been reported previously[12].

The biological samples consisted of films of whole and broken chloroplasts from plants and algae, and chromatophores from photosynthetic bacteria. The samples were prepared according to well established experimental procedures[13,14], and the films were obtained by evaporation, in a mild air flow, of aqueous suspensions of the photosynthesis systems. Partial dehydration of the samples did not alter the primary photo-events, which were monitored by the measurement of light-induced electron paramagnetic resonance signals[15,16], and of light-induced absorbance changes, indicating bleaching of the reaction centre pigments[1,16]. The films were deposited on microscope cover slips, and were located, in the microwave cavity, at the antinode of the microwave electric field, by means of styrofoam supports. Light pulses obtained from a Xenon flash tube or a ruby laser were fed into the cavity by means of quartz light pipes. Absolute light intensities were measured at the sample location by fast silicon light detectors, with calibrations traceable to the USA National Bureau of Standards.

Our primary observables were the light-induced changes in the microwave power coupled through the bimodal transmission cavity, which are related to the photoconductivity[8]. Accompanying these, there may be changes in the real part of the dielectric constant, which are reflected as changes in the resonance frequency of the cavity[9]. On application of an external magnetic field, with particular adjustments of the bimodal cavity, the power coupled through the cavity is related to the Faraday rotation of the sample[11]. When the cavity is imperfectly adjusted the photoconductivity and Faraday rotation signals are superimposed, but can be separated.

Figure 1*a* is an example of a photoconductivity signal, $\Delta\sigma$, from a sample of chloroplasts of *Spinacia oleracea*. As $\Delta\sigma = \Delta n q \mu$, where Δn is the change in number of carriers of charge, q, and mobility, μ, it is necessary to determine μ to obtain values of Δn; otherwise the data are only qualitative[7]. Light-induced changes in carrier mobility were negligible, and thus did not contribute significantly to the observed photoconductivity. Estimation of the quantum yield for carrier generation, $QY = \Delta n$/quanta absorbed, required knowledge of the changes in carrier concentration Δn, and the quanta absorbed by the sample. The Hall mobility, $\mu_H = \theta_H/B$, can be obtained from measurements of the Faraday rotation, where θ_H is the Hall angle, or angular rotation of the carrier current on application of an external magnetic field of intensity B. Figures 1*b* and 1*c* are examples of Faraday rotation signals, for a value of $B = 10^4$ gauss, superposed on photoconductivity signals. In Fig. 1*b*, the settings were such that a negative carrier would produce an upward deflection, positive carriers would produce a downward deflection. These Faraday rotation signals add algebraically to the photoconductivity signal of Fig. 1*a*. The early temporal component in Fig. 1*b* is larger in magnitude than the corresponding portion of Fig. 1*a*, thus establishing its origins in negative carriers. The later temporal components in Fig. 1*b* are of opposite sign to the early component, and subtract from the photoconductivity signal of Fig. 1*a*. They are thus attributed to positive carriers. In Fig. 1*c*, the experiment was repeated with the direction of the external magnetic field reversed. The field-dependent components reverse their deflection directions, and the early temporal components subtracts from the photoconductivity signal of Fig. 1*a*, whereas the latter components add to it. The sum of Fig. 1*b* and 1*c* removes the magnetic field-dependent signals, while their difference removes the photoconductivity signal. The reversal of the field-dependent signals on reversal of the sign of the external magnetic field, established the origins of these signals as Faraday rotations.

The Hall mobilities as calculated from Fig.1 are of the order of 1 $\text{cm}^2\ \text{V}^{-1}\ \text{s}^{-1}$. Using this value of μ, we calculated the number of positive carriers as $10^{13}\ \text{cm}^{-3}$ for saturating intensities of actinic light, and quantum yields around 1% for non-saturating illumination levels.

Data, similar to those shown in Fig. 1, have been obtained from leaves and chloroplasts of other green plants and algae, and from chromatophore fragments of the photosynthetic bacterium *Rhodopseudomonas spheroides*. Notably, the non-photosynthetic mutant of this organism, PM-8, gave rise to signals one to two orders smaller in magnitude, than those exhibited by the photosynthetically active varieties, and did not exhibit the sign reversal in the Faraday rotation experiments.

Figure 2 shows the wavelength dependence of the microwave photoconductivity signals for a sample of spinach chloroplasts similar to that from which the data of Fig. 1 were obtained. This dependence generally parallels that for photosynthesis[18], aside from an increase towards the longer wavelength, where the reaction centre pigments absorb. A similar long wavelength

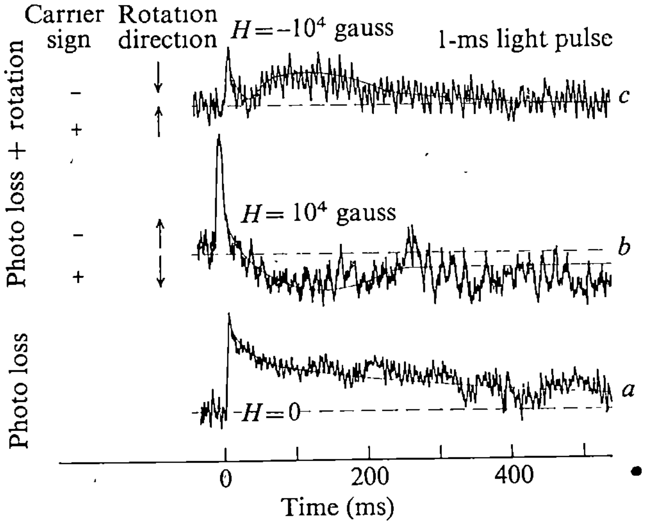

Fig. 1. Microwave photoconductivity and Faraday rotation signals from a spinach chloroplast film The photoconductivity signal, trace *a*, exhibits both fast and slow components. In *b* a Faraday rotation signal adds algebraically to the photoconductivity of *a* so that the early temporal components attributable to negative carriers add while the later components subtract. For the opposite direction of magnetic field, *c*, the Faraday rotation signals reverse sign while the photoconductivity maintains the original sign, thus leading to a subtraction of the signal for the negative carriers.

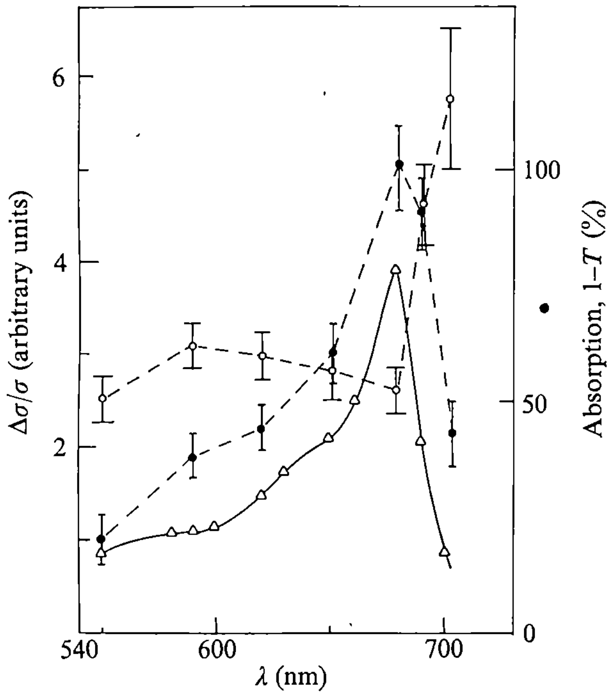

Fig. 2. Action spectrum and relative quantum yield for the microwave photoconductivity in a spinach chloroplast film. △, Absorption spectrum of the sample; ●, action spectrum, ○, relative quantum yield. The points are normalised to constant incident light intensity at 550 nm.

increase was also observed in the photosynthetic bacteria.

Superposition of pulsed light on steady background illumination, is a standard procedure in semiconductor physics to study trapping processes[10]. Such procedures were used in our experiments; they provided evidence for the trapping of carriers of both signs, and facilitated a rough determination of the trap concentration of ~ 10^{13} cm^{-3}. The number of reaction centres, estimated from the chlorophyll content of the sample, was also ~ 10^{13} cm^{-3}. Arrhennius plots of the temperature dependency of the photoconductivity signals and their decay times, gave activation enthalpies of 0.3 eV.

Light-induced changes in the real part of the dielectric constant, $\Delta\varepsilon'$, of ~ 10^{-5}, were observed. Changes in the dielectric constant can be related to changes in volume polarisability, α, using the Clausius–Mossotti relationship[10]. From this value of $\Delta\varepsilon'$, we calculated a value of $\Delta\alpha$ of 10^{-20} cm^3. Assuming that α approximates the volume over which the charges are separated, $\alpha^{1/3} = 3\times10^{-7}$ cm, represents a separation length. This value is comparable with the presumed size of the pigment–protein complex of the reaction centre[19,20].

In the bacterial chromatophores the light-induced ESR signals exhibit decay half-life regimes of 30–50 ms, and of several seconds; the positive carriers exhibit very similar kinetic components. The reaction centreless mutant, *PM-8*, exhibits neither Faraday rotation, nor photo-induced ESR signals. Titration of the chromatophores with ferricyanide to maximum dark ESR signal intensity, concurrently eliminates the slow components of the photoconductivity signals. Taken together, these observations point to a common origin for the ESR and positive carrier photoconductivity signals.

The positive carrier component is thus interpreted as originating in the same species that produced the ESR signal I, the dimeric chlorophyll cation radical[20,21], and we suggest that this species behaves as a mobile hole (over a volume of 30° $Å^3$), when observed at microwave frequencies. The negative carrier component of the photoconductivity (few ms range) is tentatively interpreted as arising from electrons thermally released from the primary acceptors (the reverse process), and its decay as resulting from charge transfer to secondry acceptors; because of their larger energy gap, they would not contribute significantly to the population of the conducting state. Rigorous interpretation of the observed activation enthalpies is seriously hindered by the fact that they may represent a combination of activations for both carrier types, and it is not possible to separate their contributions from the available data.

The general behaviour, therefore, can be understood in terms of photoliberated charges migrating for short distances through a dielectric medium. The microwave Hall mobilities are incompatible with charge transport through conduction bands; rather, they are similar to those expected for tunnelling or hopping processes[10].

These observations and interpretations, which will be elaborated fully elsewhere, strongly support the model in which the primary charge separating events occur in the reaction centres in photosynthesis. The fact that such signals are not observed in the reaction-centreless mutant of *R. spheroides*, together with stringent controls, and other evidence not reported here, rules out an artefactual source of the signals. The action spectra for the microwave photoconductivity, resembling, as they do, those for photosynthesis, point to a close connection between the two processes. The number of traps, as well as the maximum number of free carriers, approximates the number of reaction centres, thus connecting the observations with the structure of the photosynthetic unit.

Kinetic evidence for a conformational transition in rhodopsin

AFTER light absorption, rhodopsin decays through a series of spontaneous reactions[1–10], the kinetics of which have been the object of considerable study. In a variety of conditions the decay kinetics of bathorhodopsin (prelumirhodopsin), lumirhodopsin, and metarhodopsin I (meta I) have been found to be non-first order, but are consistent with a set of parallel, independent first-order reactions[2–10]. These kinetics have been assumed to result from the existence of multiple forms of each of these intermediates, and it has been proposed that rhodopsin itself exists in different forms or different environments in some conditions[7]. The kinetics of meta I → meta II in both dodecyltrimethylammonium bromide- and digitonin-solubilised phospholipid-free rhodopsin are also consistent with two forms of meta I which decay independently (J. G. S. and E. O. Plante, unpublished). We show here that the effect of temperature changes on these kinetics is consistent with the hypothesis that rhodopsin exists in two forms in equilibrium resulting from the accessibility of two stable conformational states separated by a small difference in free energy.

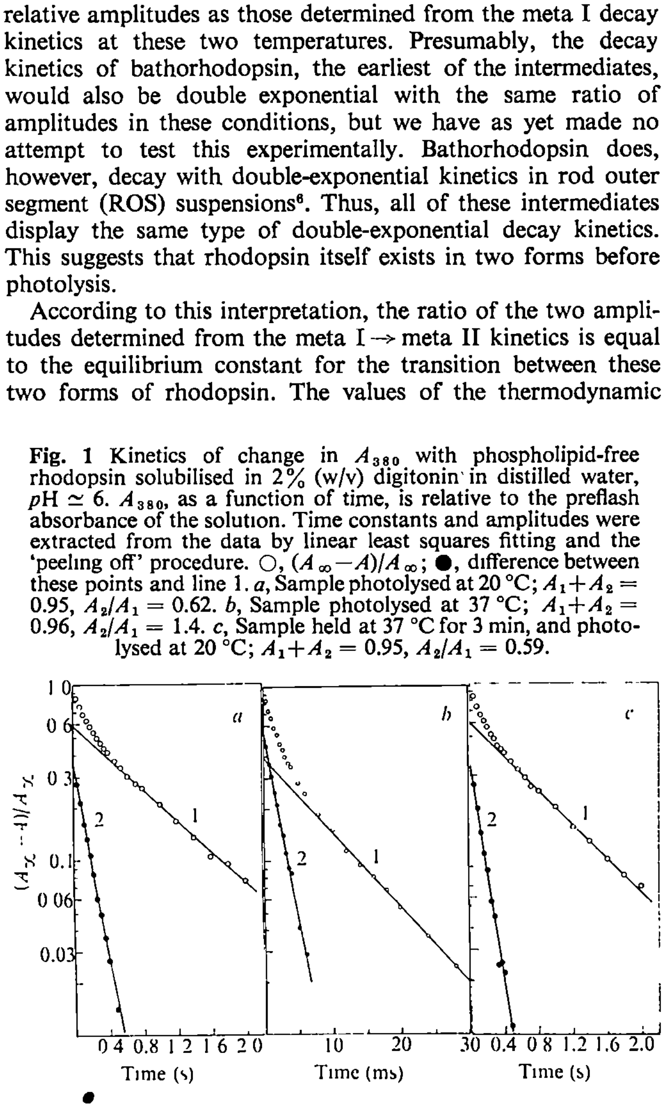
We have studied the kinetics of rhodopsin decay reactions using flash photolysis of detergent-solubilised rhodopsin containing less than 0.2 mol phospholipid per mol rhodopsin. The kinetics of meta I → meta II were determined from absorbance measurements at 380 nm and of lumirhodopsin → meta I from absorbance measurements at about 415 nm, which is near the isosbestic point of meta I and meta II. In each case the absorbance against time function could be fitted by a sum of two exponential decay functions of the form $\Sigma A_i \exp(-t/\tau_i)$. We used a phospholid-free preparation so that we could exclude phospholipid heterogeneity of the digitonin micelle as a source of multiexponential kinetics.

We have assumed that these kinetics result from the independent decay of two forms of each of these species, and thus that the amplitudes of the two exponential terms are proportional to the initial concentrations of these two forms. Figure 1 shows that for meta I → meta II a change in temperature from 20 to 37 °C results in a change in the ratio of these two amplitudes, but not in their sum (Fig. 1*a* and *b*). Furthermore, this change is reversible (Fig. 1*c*). Such kinetics are caused by two components which are interconvertible, but only on a time scale which is long compared with the time constants for decay of meta I. Thus, these two components exist in equilibrium, but this equilibrium is established before the appearance of meta I.

We also found that the kinetics of decay of the earlier intermediate, lumirhodopsin, at 20 and 30 °C were consistent with double-exponential kinetics with approximately the same relative amplitudes as those determined from the meta I decay kinetics at these two temperatures. Presumably, the decay kinetics of bathorhodopsin, the earliest of the intermediates, would also be double exponential with the same ratio of amplitudes in these conditions, but we have as yet made no attempt to test this experimentally. Bathorhodopsin does, however, decay with double-exponential kinetics in rod outer segment (ROS) suspensions[6]. Thus, all of these intermediates display the same type of double-exponential decay kinetics. This suggests that rhodopsin itself exists in two forms before photolysis.

According to this interpretation, the ratio of the two amplitudes determined from the meta I → meta II kinetics is equal to the equilibrium constant for the transition between these two forms of rhodopsin. The values of the thermodynamic parameters for this hypothetical transition were calculated from the temperature dependence of the equilibrium constant in the range 20–37 °C (Fig. 2). For phospholipid-free rhodopsin solubilised in 2% (w/v) digitonin in distilled water, $pH \simeq 6$, $\Delta H^0 = 9.8$ kcalorie, $\Delta S^0 = 32$ e.u., and at 37 °C, $\Delta G^0 = -0.2$ kcalorie. These values are of approximately the same magnitude as those reported for transitions between some conformational substates of α-chymotrypsin[11,12]. Two components in these kinetics could also be due to the availability of two different environments in the digitonin micelle, but we have recently obtained similar results with ROS solubilised with cetyltrimethylammonium bromide, Emulphogene BC720, Amonyx-LO and with detergent-free suspensions of sonicated ROS. Thus, it seems likely that the heterogeneity inferred from these kinetics resides in the state of the protein itself.

Fig. 1 Kinetics of change in A_{380} with phospholipid-free rhodopsin solubilised in 2% (w/v) digitonin in distilled water, $pH \simeq 6$. A_{380}, as a function of time, is relative to the preflash absorbance of the solution. Time constants and amplitudes were extracted from the data by linear least squares fitting and the 'peeling off' procedure. ○, $(A_\infty - A)/A_\infty$; ●, difference between these points and line 1. *a*, Sample photolysed at 20 °C; $A_1 + A_2 = 0.95$, $A_2/A_1 = 0.62$. *b*, Sample photolysed at 37 °C; $A_1 + A_2 = 0.96$, $A_2/A_1 = 1.4$. *c*, Sample held at 37 °C for 3 min, and photolysed at 20 °C; $A_1 + A_2 = 0.95$, $A_2/A_1 = 0.59$.



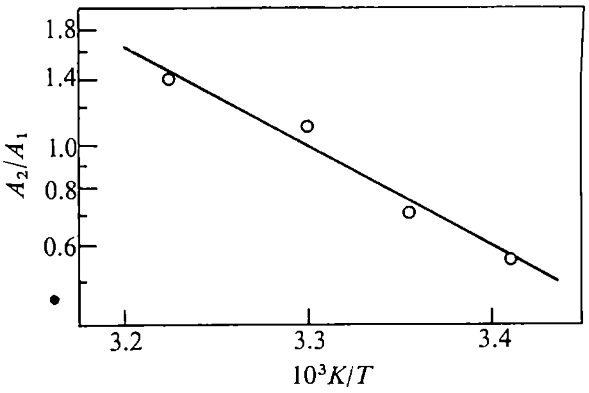


Fig. 2 Van't Hoff plot for the proposed reaction $R_1 \rightleftharpoons R_2$ over the range 20–37 °C. At each temperature, A_1 and A_2 were determined as described in Fig. 1. A straight line was fitted to the data points by linear least squares, giving $\Delta H^0 = 9.8$ kcalorie and $\Delta S^0 = 32$ e.u.

Erratum

In the article "Seismic evidence for local undulation of olivine–spinel phase boundary", by S. K. Dey-Sarkar and R. A. Wiggins (*Nature*, **257**, 572; 1975) the last two sentences of the first paragraph should read: While analysing seismograms between 14 and 18°, a group of anomalous data was observed localised in a specific region which could be explained only by a local undulation of the 410-km discontinuity. Here we present these observations and give a speculative explanation for the undulation.

obituary

John Morrison Barnes, CBE, Director of the MRC Toxicology Unit, Carshalton, died after a short illness on September 24 at the age of 62.

Dr Barnes studied medicine at the Universities of Cambridge and Sheffield and graduated in 1936 He received his early training in research in the laboratory of Howard Florey at Oxford, where he studied lymphocytes and also carried out very important initial toxicity tests on penicillin. He then collaborated with J. Trueta on work related to war injuries, including research on limb ischaemia, the absorption of bacterial toxins from tissues and the treatment of burns. He joined the Royal Army Medical Corps in 1942 and spent the next three years at the Defence Establishment at Porton, with which he remained closely associated as an adviser for the rest of his life. In 1947 he was responsible for setting up the MRC Toxicology Unit at Carshalton which, from very small beginnings, grew under his directorship to become one of the largest establishments of the MRC. The guiding principle of nearly all the research at the Toxicology Unit was derived from the concept of Claude Bernard that toxins could be used to elucidate physiological processes coupled with the ideas of the biochemical lesion and of lethal synthesis, due to Peters Many toxic substances were studied, Barnes himself being particularly interested in the toxicology of beryllium, organophosphorus compounds, organotin compounds, nitrosamines, aflatoxin and carbon disulphide. Barnes was perhaps best known internationally for his work on organophosphorus and carbamate pesticides. The Unit became a World Health Organisation International Reference Centre for the Evaluation of the Toxicity of Pesticides in 1967 and Barnes advised the Ministry of Agriculture on medical aspects of pesticides for many years. He produced an invaluable guide, *Toxic Hazards of Certain Pesticides to Man* (WHO Monograph 16). Because of his impressive depth of scientific knowledge combined with his great practical common sense, Barnes was uniquely in demand as an advisor on all aspects of possible hazards from environmental and occupational exposure to toxic chemicals. He was a member of numerous Governmental and other advisory committees including the British National Committee for Problems of the Environment. He served on the editorial boards of several scientific journals and was made Visiting Professor of Pharmacology at King's College, London in 1967. Barnes had considerable skill as a laboratory bench worker but little opportunity to exercise it in his later years because of the punishing load of advisory and administrative work that he willingly undertook. His unobtrusive help and guidance was greatly valued by his colleagues and had he been less unselfish, his output of original published work could have been much greater. John Barnes contributed more to the establishment of toxicology as a scientific discipline than anyone in this country and perhaps in the world.

P. N. Magee

Professor J. C. Pócza, Head of the Department of Structure Research of the Research Institute for Technical Physics of the Hungarian Academy of Sciences, Budapest, died on September 10. Born in 1915, he graduated from the University of Szeged in 1938 and obtained his Ph.D. at Budapest University in 1945.

Professor Pócza first worked on structure determination by X-ray diffraction and then, as assistant at the Institute of Nuclear Physics, took part in the first lunar-echo measurements, carried out under the direction of Professor Z. Bay.

He entered the field of thin film physics in 1954, studying the thin-film growth processes by electron microscopic *in situ* methods. He was a member of the International Committee on Thin Films, a member of the Editorial Board of Thin Solid Films, and was the Chairman of the 3rd International Thin Film Conference held in Budapest this summer.

For many years he was the deputy general secretary of the Hungarian Eötvös Loránd Physical Society and a member of the Hungarian National Committee of IUVSTA.

J. L. Harper, J. S. Sawyer and **E. A. Vincent** have been appointed new members of the Natural Environment Research Council.

International meetings

November 12, **A new look at pollination,** Kent (The Principal's Secretary, Wye College, Ashford, Kent, UK).

November 12, **Life-games with glass beads and molecules,** Cambridge (The Secretary, Department of Chemistry, Lensfield Road, Cambridge, UK).

November 21, **The scientist as a leader,** London (The Industrial Society, PO Box 1BQ, Robert Hyde House, 48 Bryanston Square, London W1H 1BQ).

December 2–3, **Grass weeds,** Paris (European Weed Research Society, c/o ARC Weed Research Organisation, Begbroke Hill, Yarnton, Oxford OX5 1PF, UK)

Person to Person

London–Rio de Janeiro exchange. London house available for one year from about February 1976, in exchange for house or flat in Rio de Janeiro. Four bedrooms and garden (Dr C. J. Sanderson, 26 Olive Road, Cricklewood, London NW2 6TX, UK; (01) 452 8364)

There will be no charge for this service. Send items (not more than 60 words) to Holly Connell at the London office The section will include exchanges of accommodation, personal announcements and scientific queries We reserve the right to decline material submitted. No commercial transactions.

Asking questions about university research . . .

UNIVERSITY bashing is a popular pastime in the UK at the moment. True, all forms of public expenditure are bound to come under scrutiny when a country is trying to keep control of a serious economic situation, but the universities are rather better than average sitting targets because it is much easier to question the expenditure of several hundred million pounds on them than to justify it in a way that convinces the holders of the purse strings. On a slightly more detailed level, asking a question like: "Why do that particular kind of scientific research?" is easy; answering it is not.

Nobody pretends, of course, that one can find out much about as complex a beast as 'university research' by talking to two, or even ten, people. The Science Subcommittee of the House of Commons Select Committee on Science and Technology, for example, must be truly fed up with asking a question of a witness, only to be told that the query should be addressed to someone else (usually unspecified) because it is outside that witness's brief, remit or responsibility. Equally, 'ologists' of the Select Committee on Science and Technology often feel that key questions are not asked or pursued—often, it must be added in the select committee's defence, because time simply does not permit.

The objections of many of those who carp about the amounts spent on scientific research in universities stem from the supposed antipathy between universities and industry. The stereotyped picture is one in which industry complains that university training in research often does not suit the industrial environment; the universities reply that a major part of their function is to acquire new knowledge and that industry should not expect a model industrial scientist to step off a university production line.

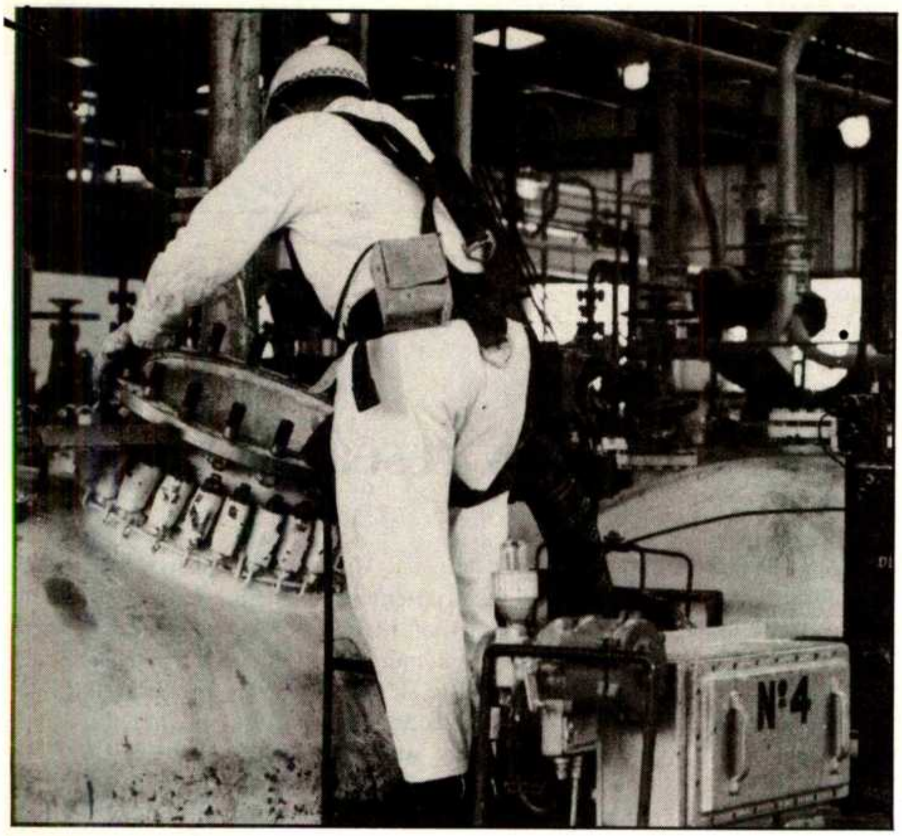
Fortunately things are not nearly as polarised as that, but there certainly are problems, and it is therefore a particularly important event when the select committee talks to industry, be it the Confederation of British Industry (CBI) or individual industrialists, about university research. It so happens that the select committee had the CBI before it last week, and one is therefore prompted to set up a list of some of the more important matters that might be covered in future select committee discussions with industry. Some of these came up at the recent meeting; some did not.

- How can the link between 'research' and 'application' be made less tenuous?
- How can the requirements of industry for, broadly, 'trained' people be squared with the universities' aim of producing 'educated' people?
- To what extent is university research compatible with the goal of much of industrial effort ('improvement' as opposed to 'innovation')?
- In what light do industrialists regard polytechnics? Should they be encouraged at the expense of (some) universities?

. . . at Cambridge in particular

IN the concluding remarks of a paper on 'useful' research carried out at the University of Cambridge (distributed from the University Offices) the late Professor J. W. Linnett said: "I have been surprised at the amount and range of useful research that is being done at Cambridge over a very wide spread of disciplines", when 'usefulness' is judged "in economic and social terms of a simple and direct kind".

This is an important statement for a man who was until a month or so ago Vice-Chancellor of the University of Cambridge to have made, even allowing that he had set out to tackle the problem of bolstering up the public image of universities. Interestingly, the standard university response to critics is also contained in Professor Linnett's paper: "Universities are places where the spirit of unfettered imaginative enquiry should be fostered". Adding his two statements together leads to a very important conclusion—that unfettered imaginative enquiry in a university environment can be of considerable use in a tangible way.



Preparing polymerisers for cleaning at BP factory.

Cutting out cancers

THE UK Government recently accepted a Convention and a Recommendation, drawn up at last year's International Labour Conference, on 'international standards concerning the protection of workers against carcinogenic substances or agents'. Both documents will play their part in establishing some useful principles and eliminating past abuses. But the practical achievement will fall short of what is usually understood by 'international standards', and the proportion of actual cancers prevented is likely to be only a fraction of the potential number. Laura Swaffield reports.

THE terms set out by the International Labour Organisation (ILO) must be seen in context. First, the documents can apply only to substances known to be carcinogenic. Unfortunately, the probability is that most industrial carcinogens have not been identified as such.

The International Agency for Research on Cancer takes it as a rule of thumb that 80% of all cancers are environmentally induced, the most easily traced often by chemicals at work. According to the WHO, however, adequately documented cases of occupational cancer represent only a fraction of 1% of the total.

The medical profession's notorious preoccupation with finding a dramatic breakthrough cure is partly to blame. A sub-committee of the US National Cancer Advisory Board, which expressed its astonishment in March of this year that "the National Cancer Program does not appear to have accorded an adequate priority nor sense of urgency to the field of environmental carcinogenesis", estimated research expenditure on preventive work as "perhaps 10% of the budget"—a pattern which is fairly typical worldwide, and not just in cancer research.

Second, the ILO documents allow great latitude to the nations concerned—each, for instance, decides for itself which carcinogens are to be prohibited or controlled, and the nature of the controls.

Third, sheer economic reality places limits on how much can be done in industry. This is one reason why individual nations are given so much freedom to decide priorities.

The whole matter came under discussion at this year's XVIIIth International Congress on Occupational Health, held in Brighton. Dr E. Mastromatteo of the ILO said the future need was for international agreements on exposure levels to chemicals. But Mr M. El Batawi from WHO was more aware of financial, political and economic problems, especially in underdeveloped countries. International exposure levels, he said, were neither practicable nor desirable—but standardised international methodology could perhaps establish a 'dose-response curve' along which each government could set its own limits.

Two case histories from the UK illustrate the bounds between which a line must be drawn. In 1927, ICI patented Nonox S, an anti-oxidant containing 2-naphthylamene which was marketed to the rubber industry. By 1938, the Association of British Chemical Manufacturers had accepted that there was a cancer risk from 2-naphthylamene. ICI started screening its own Nonox S workers, and by 1942 had established a proved cancer hazard for those working with the hot finished product. Only in 1949 was Nonox S withdrawn from sale.

The story does not end there. There was no warning to customers, and one, Dunlop, waited until the mid-1950s to set up a research unit, and until 1960 to recommend the screening of employees who had worked with Nonox S. At one plant, screening did not begin until 1965. By 1970, some 450 cases of bladder cancer had come to light many too late for effective treatment.

As late as this year, the National Health Service (NHS) distributed a circular setting out the screening arrangements for workers and ex-workers in the rubber industries. Some workers who left their jobs before screening started must still be unaware they are at risk. Meanwhile, oddly enough, the NHS does not want the circular to attract great publicity because it has "limited application", even though its implications are vast and of great discredit to all concerned.

The second case, the big occupational cancer story of 1974–75, involves vinyl chloride monomer (VCM) and shows the other side of the coin. Employees' organisations were consulted from the start when a link was discovered between VCM (used in the manufacture of PVC) and angiosarcoma, a rare liver cancer. The discovery, typically, came by accident during animal research on a VCM-linked hand condition. By early 1974, epidemiological work had turned up a possible four VCM-linked angiosarcomas in the USA, and one in the UK.

The ensuing events are something of a demonstration of ideal industrial practice. The chemical industry and government agencies (in the UK, the Employment Medical Advisory Service of the new Health and Safety Commission) got together, with trade union involvement, to find out the extent of the danger and eliminate it. The then medical adviser to the Trades Union Congress (TUC), pointed out from the start that there was no case for shutting down the polymerisation process, which annually produces 10 million tons of PVC world-wide.

By June 1974, the Department of Employment was drawing up a code of practice limiting exposure to VCM vapour to 50 parts per million with a time-weighted average of 25 ppm. As late as 1959, the prescribed threshold limit value had been 500 ppm. Significantly, the code of practice required results of atmospheric sampling to be available to workers. Today, the limit in industry is fixed at 30 ppm. (time-weighted average 10 ppm.), which is thought to be the ultimate with existing plant.

This shows what industry can do if it tries. But how does the balance sheet look? In the UK alone, £13 million has been spent since 1974 on research and alterations to plant. Four companies with a total of 500 workers are involved.

But the total of deaths in the UK now found to have been due to VCM-induced angiosarcoma is two—one a man of 71, the other a man with a long history of liver abnormality. The world-wide score is under 40, not all of them confirmed.

With thousands of new chemicals coming into use every year, it is only too clear that any attempt to trace and control all carcinogens, even where deaths have already occurred, would bankrupt the world chemical industry in no time. It is up to individual nations, therefore, to decide what is an acceptable risk, socially and economically.

The ILO Convention, within these limits, requires "every effort" to be made to replace or control carcinogens, all available information to be given to exposed or formerly exposed workers, relevant tests to be carried out on all workers (although there is no provision that the results be communicated to them) and government supervision throughout.

There is also an important requirement that "an appropriate system of records" be kept. Death notifications and employers' records have been instrumental in tracing VCM and Nonox S workers, and record systems are the essence of occupational control where a carcinogen is discovered.

The Recommendation—a less binding formulation for signatories than the Convention—goes much further than the Convention. Most of the extras concern information: the national "competent authority" is to promote epidemiological studies, collect and disseminate all available information, produce "educational guides" for both employers and employees, and try to establish criteria for determining carcinogenicity.

Employers have a duty to seek out information, carry out studies with the aid of the competent authority, notify all affected workers and instruct them regularly. Employers' and workers' organisations both have a duty to carry out information programmes and encourage full participation by workers in control programmes.

The Nonox S story shows how necessary such measures can be, especially in countries (like the UK in the 1940s) with an undeveloped system of safety law enforcement and worker participation.

But implementation could also be a tall order in many countries, and even the UK, which now probably leads the world in health and safety legislation, has confessed that 'it will take a considerable time to set up suitable systems.'

International cooperation on occupational health research is acknowledged to be very poor at present, quite apart from the unsatisfactory distribution of the research effort itself. The ILO's ideas on information could point the way to making use of what information there is. But it seems a pity they are tucked away in a mere Recommendation. ☐

HEALTH and safety legislation in the UK has traditionally been of the Old Testament type—detailed rules with penalties for non-compliance. This had its disadvantages. The Factory Inspectorate, for example, being hopelessly undermanned, was forced into a soft-footed approach rather than waste valuable inspecting time in court taking prosecutions which led to derisory fines even for fatal negligence.

Progress came through the Common Law which enshrines a New Testament-style duty to care for one's neighbour and leaves the practical details to the individual. It was under Common Law, for instance, that two Dunlop employees with bladder cancer were able to obtain damages in 1971 from ICI, which had no legal responsibility to them under the Factories Acts.

Claims for damages have done much to clarify the responsibilities of both employers and employees. Moreover, it was the first successful damages claim for hearing loss induced by noise at work which led to a business boom for the manufacturers of protective equipment—and has made the Department of Employment's code of practice on noise (not statutorily binding) a best-seller.

Purpose-built Old Testament legislation is usually narrow in its usefulness, and in modern industrial conditions may be out of date as soon as the ink is dry. In the UK the new Health and Safety at Work Act, which came into force this year, and unifies the Factory and Alkali Inspectorates into one Safety and Health Executive, goes as far towards the flexible New Testament approach as is possible.

It imposes a slightly more detailed duty of care on employer, employee and supplier. But old detailed regulations built up over a century remain in force, and will be expanded, together with the more recently produced codes of practice.

Replacing the old penalties is a system of improvement and prohibition notices which oblige a manufacturer actually to shut down a process until it is made safe to the satisfaction of the relevant inspector. Arguments about notices are dealt with by the industrial tribunals, leaving the inspector to inspect and hand out notices. This puts a high price on failure to comply with the inspector's recommendations. In serious cases, the executive is free to prosecute on indictment, and the duty of care makes it reasonably clear who is to be prosecuted in each case taken. A jury verdict of guilty will lead to an unlimited fine, or perhaps even to imprisonment.

The picture elsewhere in the world mirrors the unsatisfactory state of pre-1975 UK legislation. Most EEC countries have detailed regulations about the provision of occupational health services in industrial companies. In practice, however, the carefully provided nursing services do little except routine curative work, which leaves out preventive work and epidemiology.

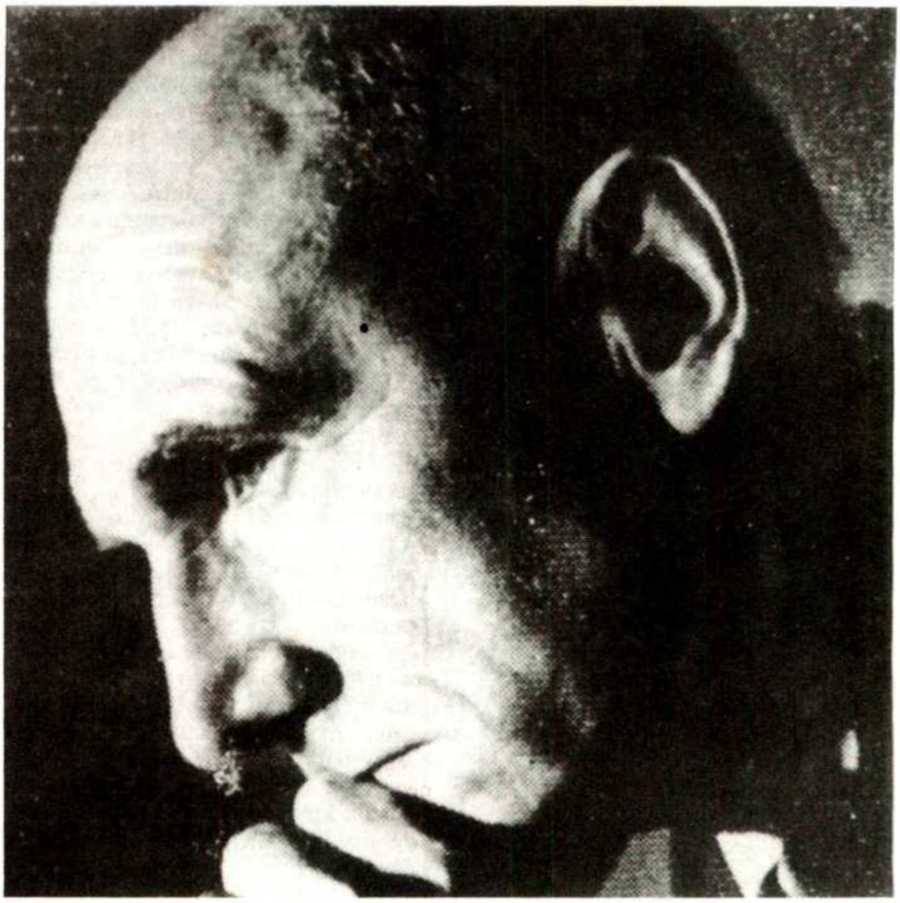
The USA has far-reaching and stringent safety and health laws on the Old Testament line—plus a tiny inspectorate which, it is estimated, is able to visit each factory about once every 400 years.

In the USSR, where there is no clear distinction between employer and employee in industry, the unions lack the sort of power exercised in the UK and the USA. Overall responsibility for safety and health is with government and the unions. Numerous state agencies are also involved —44 of them, for instance, in the development of the Lada (Fiat) car factory under licence from Italy. The result is often confusion and, occasionally, inaction.

Nobel award to Prelog

PROFESSOR Vladimir Prelog of the Federal Technical High School (ETH) in Zürich has been awarded half of the Nobel Prize for Chemistry, at the age of 69, for his work on stereochemistry. It comes to him not so much for any one outstanding discovery, but for a lifetime's work in chemistry which has produced a steady succession of significant researches combining deep thought and elegant experimental work. van't Hoff is considered as the founder of 'Chemistry in space'; Prelog has been the High Priest of this cult for the past 20 years.

Prelog was born in 1906 in Sarajevo in the Austro–Hungarian Empire. He studied in Prague, worked in industry, and then joined the staff of the University of Zagreb in Yugoslavia. Fortunately for Prelog and for chemistry, he found his way to Switzerland in 1941 and joined the great ETH School of Organic Chemistry. His career in Zürich was naturally influenced by his predecessor, Professor L. Ruzicka (Nobel Laureate, 1939), whom he succeeded in 1957. Prelog's structural and synthetic studies on natural products have covered a wide range, including terpenes, steroids, alkaloids and antibiotics.



Vladimir Prelog

A major stereochemical interest started from the preparative work of the Zürich school on medium and large rings, and developed into Prelog's studies on transannular reactions. In the spirit of his time, Prelog not only made new compounds by ingenious methods, but studied their physical properties and their reactivity, using all of the steadily increasing range of tools provided by physical chemistry.

His work in stereochemistry has included a considerable share in the study of conformations, for example, his pioneer work on asymmetric synthesis and the medium-ring work noted here. He delivered one of the earliest Centenary Lectures to the Chemical Society in London in 1949; this significantly influenced the thinking of other pioneers of conformational studies.

Prelog's ability to get to the heart of things is nowhere better illustrated than in the work on the Sequence Rule. This work, the result of a very fruitful partnership between Prelog, the late Sir Christopher Ingold and Dr R. S. Cahn, soon developed into something much more than a method for designating stereoisomers (the "*R* and *S*" system). It led Prelog to consider in a simple, but fundamental way, the geometrical basis of stereochemistry.

The Sequence Rule papers first showed clearly and in a systematic framework of thought the nature of axes and planes of chirality. (The term "chirality", borrowed from Kelvin, has been universally accepted as a convenient term for the property of "handedness".) The need to test the Sequence Rule exhaustively during its development caused Prelog to visualise, and then to make with his students, organic compounds of widely differing types displaying stereoisomerism of kinds apparently unknown in nature, and hitherto unsuspected by organic chemists—for example, cycloenantiomers and cyclodiastereoisomers.

In all of this, Prelog has carried to its logical conclusion the concept of the tetrahedral atom (van't Hoff and Le Bel). The marriage of chemistry and geometry thus arranged by Prelog, and called by him "chemical topology" is already a happy and most fruitful one. All types of stereoisomerism can be derived from the consideration of simplexes in two- and three-dimensional space, alone or in combination.

The general principles were outlined in lectures in Amsterdam, in Dublin, in Hamburg, and in Zürich (Karrer Lecture), and were presented in a more extended from in lectures at Cornell. Some of these ideas have now appeared in a very general paper modestly entitled "Pseudoasymmetry in organic chemistry", which was followed by two detailed papers on compounds showing axes and planes of pseudo-assymetry, giving some experimental 'meat' to cover the elegant geometrical skeleton. The international group characteristically addressed by Prelog in letters as *Stereofreunde* await with great interest and some impatience the fuller story.

Much of Prelog's recent work has been on the borders of chemistry and biochemistry, including his studies on enzymatic reactions. In addition to their supreme biochemical importance, enzymatic reactions provide a suitable terrain for thinking in terms of two-dimensional chirality.

Like many continental professors, Prelog has long had close connections with industry, and he has been for some years a Director of Ciba–Geigy in Basel.

He is a frequent and welcome visitor to laboratories all over the world—and nowhere more welcome than in the UK. Few chemists offer more stimulating discussion to collegues of all ages and interests. He is always one of the liveliest disputants at any meeting, and he was one of the founding fathers of the annual Bürgenstock Conferences on Stereochemistry.

The *Stereofreunde* rejoice in this award to Prelog. Perhaps the pilgrimage to Stockholm will usher in an age of many-dimensional stereochemical thinking.

international news

US energy policy criticised

by Colin Norman, Washington

IT was just two years ago that former President Nixon coined the term Project Independence as the rallying cry for the drive to make the United States self-sufficient in energy. Since then funds for energy research and development have boomed, the Energy Research and Development Administration has been established to take charge of the effort, and President Ford has reiterated at every opportunity his commitment to the goal of reducing oil imports. Although Mr Nixon's optimistic predictions that the nation could achieve energy independence by 1980 were quickly written off as unrealistic political hyperbole, self-sufficiency is still the guiding principle behind energy policy in the United States.

But, in a report which pulls few punches and which probably represents the most thorough independent analysis so far performed on the federal government's plans for energy research and development, Congress's new Office of Technology Assessment (OTA) has warned that ERDA's strategy is "inadequate" and that it has defects which could even "lead to an increased dependence on foreign energy sources". OTA has raised two broad criticisms of ERDA's programmes, and it has also faulted the agency on a host of specific points.

Prepared by six panels of experts drawn from universities, industry and non-profit institutions, the OTA study concentrated its attention on a massive two-volume plan and programme published by ERDA last June, which will form the basis of the federal government's energy research and development operations over the next few years (see *Nature*, **256**, 83; 1975). It should be noted in ERDA's defence, however, that the plan was published less than six months after ERDA was established, and it was prepared while the agency was recruiting staff and finding its feet. Inevitably, the detailed strategy reflects the sum total of the efforts which ERDA inherited from other agencies, and it's not surprising that the programmes show few significant changes in direction. Indeed, it was no small feat that ERDA managed to produce the plan at all in such a short period.

Nevertheless, OTA's two chief criticisms go to the heart of ERDA's strategy, and they merit close attention. To begin with, OTA said that ERDA's overall plan "is a significant milestone in the evolution of a long-term national energy policy", but it found that the programmes which ERDA is supporting do not "appear adequate to achieve the stated goals". The problem, OTA suggests, is that ERDA has taken too narrow an approach by concentrating almost exclusively on the development of sophisticated technology and neglecting many non-technical factors which could inhibit the implementation of new technologies. Moreover, OTA has accused ERDA of paying insufficient attention to conservation by failing to promote the development of relatively mundane technologies which could reduce energy growth in the short term.

"In addressing the energy goals, ERDA adopted a narrow, hardware-oriented approach," OTA suggests. Although such an approach may be well suited to putting a man on the Moon, or building new weaponry, OTA notes that the energy crisis is "a far more complex and wide ranging challenge". As a result, "ERDA's narrow approach to the national energy policy goals might well fulfill a mission —developing new technology—without providing an answer—a secure energy future. Unresolved 'nontechnical' issues—from inadequate incentives for commercialisation through environmental demands, competitive use of resources, to community resistance—could block the most sophisticated engineering achievement", OTA warns.

ERDA officials are, of course, well aware of such criticisms. When the plan was published last June, for example, Dr Robert C. Seamans Jr., the Administrator of ERDA, stated explicitly that "it is one thing to take a relatively small number of astronauts on an experimental-type mission. It is another thing to put into being in this country an energy delivery system and an energy conservation system which will satisfy the needs of over 200 million people . . . It is a much more complex problem we face than just the research and development".

OTA clearly feels, however, that although ERDA may recognise the need for a broad approach to energy research and development, its plan does not reflect that need. "If ERDA confines its activities predominantly to the proving of the feasibility of technological options, some other entity should address the more complex issues underlying energy solutions," OTA suggests.

A central difficulty, which OTA does not specifically address in its report, however, is that overall energy policy in the United States is hopelessly confused. Congress and the White House have been at loggerheads for months on the question of whether or not oil and gas prices should be decontrolled, for example, and Congress has not yet demonstrated that it has the stomach for taking politically unpopular decisions to curb energy growth in an election year. Energy policy, in short, has become a political football, and swift progress on the "more complex problems underlying energy solutions" should not be anticipated.

As for OTA's more specific complaints about ERDA's plans, the following are among the more important:

- Only about 2% of ERDA's budget is allocated to conservation programmes, yet "successful widespread implementation of conservation programmes . . . can have both a rapid and continuing effect", OTA suggests. ERDA may be neglecting such efforts because that are relatively mundane, and not intellectually as exciting as the development of sophisticated new supply technologies.
- Insufficient emphasis is placed on international cooperation in such areas as nuclear waste disposal, the management of nuclear materials, and the development of ocean resources.
- ERDA is not devoting enough attention to commercialisation of new energy technology. Although ERDA's plan outlines a philosophy for commercialisation, it "clearly needs a more detailed explanation and careful definition of plans for developing a mechanism for coordination with industry".
- "Only limited attention is given to socioeconomic research and analysis in addressing the nation's energy problems". Broadranging research is needed to identify non-technological obstacles to energy solutions.

Conventional wisdom is that electrical energy consumption will continue to grow as a much faster rate than total energy consumption. But OTA notes that "intensive electrification will have a noticeable social impact and may present problems of vulnerability and reliability", and suggests that "the long-term electrification approach should be more thoroughly analysed . . . to make sure that viable alternatives are not lost by default".

OTA's analysis was performed at the request of three Congressional committees which have jurisdiction over ERDA, and which are thus in a sound position to ensure that the agency changes its policies if necessary. The plan will be updated each year and republished in January along with the President's budget request. □

Re-establishment of science office

AFTER months of agitation by prominent spokesmen for the scientific community, the House of Representatives last week approved a bill to reestablish a science policy office in the White House. The Senate is expected to follow suit early next month, and the measure could be on Mr Ford's desk soon after Christmas—almost exactly three years after Mr Nixon decided that he no longer required the services of a full-time science adviser.

The bill swept through the House to the accompaniment of a chorus of laudatory remarks about the benefits which scientists can bring to the heart of national policymaking, and it was eventually approved by the impressive margin of 362 votes to 28. According to Representative Charles Mosher, a senior republican from Ohio who helped draft the measure, the bill also has Mr Ford's wholehearted support.

Scientists are therefore well on their way back to the inner corridors of power, from which they were banished by Mr Nixon in 1973 as the result of a post-election shake up of the White House staff. Mr Nixon dismantled the Office of Science and Technology, which was established by Presidents Eisenhower and Kennedy, and conferred the title of science adviser on the already overburdened shoulders of the Director of the National Science Foundation, Dr H. Guyford Stever.

Although it was fortunate that the science policy apparatus was out of the White House when it was wallowing in the Watergate morass, there have since been numerous calls—including one from the prestigious National Academy of Sciences—for it to be brought back in. As a result, Mr Ford five months ago sent Congress a legislative proposal for a rather modest office, headed by a single science adviser.

The bill passed by the House last week conforms rather closely to Mr Ford's proposal, although a few significant changes were made along the way. The office, which would be called the Office of Science and Technology Policy (OSTP), would be limited almost exclusively to advice and analysis—it would have no direct control over scientific programs or budgets. The director of OSTP would be the President's chief science adviser, and his brief would extend over most of the federal government's scientific affairs, including military technology, the economy, foreign relations, and so on. The budget for OSTP would be about $2 million a year.

As for the manner in which the office would carry out its responsibilities, the bill merely states that the director should "develop appropriate working relationships" with the National Security Council and the Domestic Council and "maintain liaison with" all other units in the President's immediate vicinity. In other words, the office would fit into the White House power structure as best it could.

During the Johnson and Nixon Administrations, the old Office of Science and Technology lost influence largely because of growing disaffection between those presidents and the scientific community, chiefly over the Vietnam War. At the finish, Mr Nixon became agitated because he disagreed with some of the advice he was receiving from the Office, particularly from the President's Science Advisory Committee—a top level independent committee chaired by the science adviser—and he banished the science advisory functions to the bureaucratic hinterlands.

Guyford Stever

After that episode, dismayed leaders of the scientific community who felt, in the trenchant words of Nixon's last science adviser Dr Edward E. David, that "science had been downgraded in national affairs", urged that a more permanent structure be established. The fact that OSTP will be set up by legislation effectively means that it cannot be dismantled simply on a Presidential whim—Congress would have to pass a bill to dismantle it.

The bill now goes to the Senate, where it is being handled by three separate committees. Hearings are already under way, and it is expected that a final version can be produced for a vote by the full Senate in December. The chief architect of the Senate's version is likely to be Senator Edward Kennedy, whose subcommittee on the National Science Foundation has a large stake in the enterprise.

Regardless of the form in which the bill eventually emerges from Congress, speculation is already rife in Washington about who will get the job of science adviser when it is established. According to sources within Congress and the Administration, the leading prospect at present is Dr Simon Ramo, an electrical engineer who is vice chairman of the board of TRW Inc, a major defence contractor. Ramo, who is widely respected in science policy circles, could not be reached for comment last week.

- For a few days last week, worried officials of the National Aeronautics and Space Administration (NASA) tried to determine the cause of an electrical failure which threatened to abort one of the two attempts to land a Viking spacecraft on the surface of Mars next year. A battery, which will be needed during the landing operation and which will also be required to power some of the experimental apparatus on the spacecraft, failed to charge when an attempt was made on October 31. The spacecraft was then about 17.6 million km from Earth. The fault was eventually traced to the charging apparatus, and on November 5, a backup charger was used. Fortunately for the $1,000 million Viking programme, it worked, and NASA officials now believe that the batteries will perform their functions according to plan.

The first Viking spacecraft, whose batteries behaved properly when they were charged last month, is now about 24 million km from Earth. It is expected to arrive at Mars about June 19 next year, and a landing attempt will probably be made on July 4—to coincide with the United States' Bicentennial. □

Canadian diary

from David Spurgeon, Ottawa

THE government of Ontario, Canada's most populous province, has started an interesting experiment in communal technology assessment this autumn. It has invited its people to help it decide directly how to provide for their future electric power needs.

At a time when economic growth is no longer sacrosanct, when consumer groups are growing increasingly critical of the siting of power stations, the placing of power transmission corridors, and the trend towards the adoption of nuclear energy, such a gesture by the province can only be seen as significant.

The method being used to gather the peoples' opinions is the Royal Commission. The Order-in-Council establishing the Royal Commission on Electric Power Planning was approved last July, and public meetings began on October 28. The commission has been instructed to examine the long range power planning concepts of the public corporation (Ontario Hydro) that is charged with providing the power needs of the province, for the period 1983–93 and beyond. It has been told to relate them to provincial planning, to the utilisation of electrical energy and to environmental, energy and socioeconomic factors, and to report, with a list of priorities, on the need for certain Ontario Hydro projects at present under consideration.

The chairman of the commission is a former professor of engineering at the University of London, Dr Arthur Porter. Porter, who now is professor of industrial engineering at the University of Toronto but on leave for a year, has long been interested in the broader implications of science and technology on society. Serving with him are an industrialist (Robert E. E. Costello, vice-president of corporate services, Abitibi Paper Company Limited), a journalist (Madame Solange Plourde-Gagnon, who will represent the consumer viewpoint), a farmer (George A. McCague, who has served on the executive of many farm organisations) and an economist (Dr William W. Stevenson, at present a member of the Ontario Energy Board).

Announcing the formation of the commission, the Provincial Secretary for Resources Development said: "The inquiry may well be the most important in this decade . . . [it] should bring into public focus basic philosophies about much of the kind of life we want for the next century and what price we are prepared to pay for its achievement . . . The public needs to know what demands for electricity will be placed upon Ontario Hydro in the long term, how these needs should be met, and what impact this would have on Ontario's way of life and its physical environment."

During the autumn, the commission will hold a series of preliminary public meetings in Ontario in 16 cities. From these it expects to learn what issues the public wants included in the main inquiry, how and in what format it should proceed, and how it can increase public participation. An attempt will be made, the commission says, "to avoid either an inhibiting or court room atmosphere . . . The preliminary meetings in particular will be very informal."

Some of the major issues and questions expected to arise are:

- Power demands have been increasing by about 7% a year. Should this rate be allowed to continue? What are the chances of its increasing or decreasing?
- How can energy be used more efficiently?
- What are the benefits, costs and risks of alternative ways of generating electrical power? What are the risks associated with nuclear generation, and the environmental implications? How long can we afford to burn irreplaceable fossil fuels?
- How can the important issues associated with land use be decided? Social, economic and environmental factors must be evaluated to decide where industrial and population growth will occur. How should this be done?
- How well are existing procedures working to guarantee public participation in land-use decisions?

One must assume that the hearings will not be equally welcomed by all involved. Recently, Ontario Hydro asked the government for permission to raise its rates by more than 25% because of the rising costs of eletricity production, and promptly found itself under heavy fire from the public and politicians. Before that, lengthy and expensive hearings were held on the subject of the placing of power transmission line corridors. And Ontario Hydro's announced intention to rely increasingly on nuclear power has drawn opposition from various quarters. All this has made the power corporation's attempts to fulfil its mandate more difficult.

Dr Porter says he fears the biggest difficulty will be to get ordinary people, outside the major interest groups, to express an opinion—and in fact to achieve good attendances at the public hearings. A former woman cabinet minister, now heading an inquiry into violence on television, found that only nine people attended a recent public meeting—inspite of what Dr Porter calls a "fantastic press". "If she can't do it," he asks, "how can we?"

The government's move to establish a commission was prompted, says Porter, by a report from Ontario Hydro on their alternative plans for provision of the province's power needs from now until the end of the century. Even assuming the lowest growth rate of power demand considered, the cost came to $20,000 million; if a 20% growth rate were assumed, on the other hand, the cost amounted to $50,000 million. With amounts of money like that involved, the corporation felt it had to draw the public into the planning.

● Another Canadian scientist who is trying to get the public involved in decisions involving science and technology is David Suzuki, a geneticist from the University of British Columbia. Five years ago, he recognised the tremendous potential influence of television, and wrote to the Canadian Broadcasting Corporation (CBC) to suggest that it should carry a television series dealing with science and society.

The result was a locally broadcast programme, Suzuki on Science, and then, last year, a job as host of a new programme called Science Magazine. The show was highly successful, but Suzuki says that because there is no basic constituency for science shows, the CBC planned to withdraw it.

According to Suzuki, the viewers objected: several hundred letters of protest were sent to the CBC, and the show will now return in February 1976 for its second season. Suzuki has also begun this year a weekly series of programmes on CBC radio, called Quirks and Quarks. In fact, he has become so busy broadcasting that he has had to take a year's sabbatical leave.

But Suzuki speaks bitterly about his scientific colleagues' interest in reaching the general public. He is cynical about their motives when they do show an interest in reaching the public, and relates it to their need for research funds for their own projects.

"Basically scientists are public servants", he said in a recent interview about another television programme he hosted, called Earthwatch. "I feel our responsibility is to de-mystify the process [of science] so citizens can participate in setting priorities." He does not portray science as being all good, and attempts to show that the scientist as an individual is a human being with all the feelings of his fellow men. □

Soviet euphoria in wake of Venus probes

from Vera Rich

THE success of the two Venus probes, Venera 9 and 10, the orbital sections of which are still gathering and transmitting data, has led to a spirit of self-congratulation, not only among those concerned with the Venus mission, but throughout the Soviet space programme generally.

This success, coming as it does in the concluding months of the present five-year plan, and in a year already distinguished by the Salyut 4 and Soyuz–Apollo missions, will undoubtedly be a considerable incentive towards increasing the space budget in the next plan

The economic justification for the Soviet space programme, as laid down by the Twenty-fourth Party Congress in 1971, is "to develop long range telephonic–telegraphic communications, television meteorological forecasting and the study of natural resources, geographical investigations and the solutions of other problems of the national economy with the aid of satellites, automatic and piloted spacecraft, and also to carry out fundamental scientific investigations of the Moon and planets of the solar system".

Although basic deep-space research does figure in this list, it seems that a need is felt to justify its importance (and cost) within the framework of the five-year plan. Accordingly, *Pravda* has highlighted not only the political significance of the Venus mission, which illustrates "how rapidly science and technology advances in conditions of socialism", but also the "terrestrial" aspect of the research carried out by the probes—by leading to a better understanding of planetary evolution, they will, it is suggested, facilitate the fuller utilisation of the natural resources of the Earth.

Pravda also carried an article from Professor A. Okhotin, of the Institute of Space Research, on the possibilities of carrying out technological processes in space. This idea has long been of interest to the Soviet space planners—preliminary electron-beam welding and cutting experiments were carried out as long ago as Soyuz 6 in October 1969—and two types of "space technology" are under consideration at present

The first is the construction of large scale orbital space stations, for astronomical and geodetic observations, prospecting, weather forecasting and environmental surveillance. Tentative plans speak of stations with a mass of hundreds of tonnes and crews of several dozen. Such stations could be constructed "most economically" in orbit, and would also require a considerable amount of repair and refit technology for their successful long term operation.

The second type of space technology under discussion involves the processing and production, in conditions of weightlessness and vacuum, of materials which would be almost impossible to produce in terrestrial conditions. The materials would include exotic metal and metal–ceramic alloys, high purity glasses, and large single crystals of semiconductors. The cost involved would, of course, be considerable, but this, says Professor Okhotin, is not the issue. Since the results of the processes would be "unique", he argues, their cost-effectiveness should not be a matter for discussion.

In the Soviet economy, where there is centralised budgetary control and planning, there is, theoretically, no need for any major expenditure to be justified to anyone beyond the higher echelons of Party or Government. Nevertheless, although no costs or estimates of the space programme have ever been published—except for vague hints that the cost of the Lunokhod-bearing Moon probes, for example, is only half that of a manned mission—there has, over the years, been a considerable undercurrent of resentment against the enormous expenditure involved.

Kremlinologists have noticed that a number of 'black' jokes have circulated on the theme of 'pie in the sky', correlating achievements in space with food shortages at home. They note that a 'soft' campaign in the Press is standard Soviet practice in preparing the population for some new government drive or campaign.

This new concentration on the cost-effectiveness of space research seems to suggest that, by forestalling possible criticism, next year's Party Congress will include in its "Theses" for the coming Five-year Plan a considerable extension of the Soviet space programme. □

Reprocessing 'scare' in Britain

by Allan Piper

IF a backbench motion at present circulating around the Houses of Parliament gains sufficient support, the reprocessing of spent nuclear fuels in Britain may well be an issue to come under the scrutiny of the Select Committee on Science and Technology during the next Parliamentary session The matter came to the fore a couple of weeks ago when some newspapers raised a furore over negotiations which could result in the transport of irradiated Japanese nuclear fuels to Britain for reprocessing at Windscale in Cumbria.

The Parliamentary moves may well have arisen directly from that publicity. But so far the initial press hysteria has signally failed to provoke any other reaction of consequence, and even the 80 or so Members of Parliament who have already signed the motion—and who, according to some reports, can expect wide ministerial support—have chosen a sensibly judicious response to claims that Britain is in danger of becoming a "nuclear dustbin".

Most informed observers are agreed that such misplaced concern can only have sprung from a complete ignorance of both the probable terms of the eventual contract and the overall picture of the British nuclear industry. The deal, which could be worth £300–500 million to Britain, depends on Japanese agreement to take back an amount of waste equal to that produced by the reprocessing.

It is likely also that the British Government will insist that the contract include a clause releasing British Nuclear Fuels (BNFL), which owns the Windscale plant, from its obligations should it fail to develop a successful technique for vitrifying the radioactive waste.

So far the Japanese have shown no signs of baulking at those conditions, which effectively mean that even after the deal has gone through Britain will be left with no 'extra' waste. She will not in any case have to accept Japanese material unless a safe way of transporting its products is developed.

Moreover, the quantity of material which the Japanese will send to Britain—4,000 tonnes will be delivered to Windscale during the decade following 1979—is hardly significant even by comparison with the 1,500 tonnes already reprocessed annually in the UK. (A considerable proportion of this, incidentally, comes from British designed, first generation magnox reactors operating in Latina in Italy and Tukai Mura in Japan.)

Even if the quantity of Japanase material is considered on its own, the figures are rather misleading to the uninitiated: of the incoming 4,000 tonnes of irradiated fuel only some 3% eventually winds up as the potentially dangerous, waste fission products which have aroused the press. Of the rest, about 95% comes out as depleted uranium—which has virtually no radioactivity—and less than 1% becomes fissile plutonium, itself a useful nuclear fuel.

As both of those latter products have some utility—depleted uranium, which is extremely dense, is fast replacing lead in many areas of technology—it seems likely that the Japanese will willingly repossess them along with the waste itself. So, all in all, there will be very little foreign material remaining in the "dustbin".

There are other reasons, quite apart from the statistics, why Britain should wish to undertake the reprocessing of foreign nuclear fuels. First, there is a strong political argument. The Japanese approached BNFL in the first place because their own government will grant licences to operate nuclear plant only if provision can be made to reprocess irradiated fuel. Like virtually every other developed nation Japan is now committed to the development of nuclear power as an energy source, at least for the next couple of decades.

In those circumstances there is really very little reason why Britain, which not only has almost 25 years of valuable and highly regarded experience in the reprocessing field but is also a signatory to the Non-Proliferation Treaty, should discourage a move which ensures that Japan does not develop the wherewithal independently to obtain plutonium and, thus, nuclear weaponry.

There are also sound financial reasons why Britain should continue the negotiations. The fuel which the Japanese hope to send to Windscale will come from American designed boiling water and pressurised water reactors. Like the latest generation of British reactors, these use uranium oxide rather than metallic uranium. Although the existing facilities at Windscale can reprocess only the latter type of fuel, used by magnox reactors, it is expected that the deal will include a Japanese downpayment of at least £100 million towards the cost of a new £300 million oxide reprocessing plant that Britain will in any case need for her own requirements in the 1980s.

Meanwhile, the final outcome of this latest controversy over what has become something of a hardy perennial in Britain remains to be seen. ☐

Votes in sewage?

KENNETH MELLANBY

OUR politicians complain of public apathy. Meetings held during the last General Election were usually badly attended In many country districts even the appearance of a Cabinet Minister only produced a handful of listeners, and the platform party often outnumbered the audience. It was surprising to find recently in the Huntingdonshire village of Warboys that when the Parish Council called a meeting to discuss the proposal to turn a clay pit on the edge of the village into a dump for toxic wastes, more than 500 people representing every section of the population, turned up.

Concern for conservation of the environment is usually a middle-class, rather elitist preoccupation, and the mass of the population is either apathetic or hostile Attempts to save ancient buildings, even those of sufficient merit to be "listed" by the Department of the Environment, may be criticised by local councillors who state that these ruins would be better pulled down and replaced by supermarkets, bingo halls or public conveniences. There is little support from all but a minority for setting up nature reserves. It is generally believed that there is little support for spending public funds on such activities as improved sewage works The Warboys meeting suggests that this last assumption may be wrong, and that there may indeed be votes in sewage.

The Warboys affair is a complicated story The London Brick Company operates a small works there, using clay dug out of nearby ground. This has produced a deep pit covering about 30 acres. Such holes are now valuable, as our affluent society finds it increasingly difficult to get rid of many types of waste. London Brick has several other holes, and operates a waste tip in Bedfordshire under the somewhat significant trade name of "Easidispose". The company applied for planning permission to use the Warboys pit for the disposal of refuse, including poisonous wastes This was opposed by the Parish Council, but it was overruled by the County Planning Committee which gave planning permission, though only under stringent conditions aimed at protecting the local environment.

The people of Warboys were not satisfied. Like other citizens of the old county of Huntingdonshire, which was engulfed in Cambridgeshire on April 1, 1974, they were suspicious of the new authority, and complained that they were being used as a dump—no similar scheme existed in Cambridgeshire, which sent its toxic wastes to Pitsea in Essex. Notwithstanding assurances from the county staff, they were not convinced that the dump would be safe. The information provided by London Brick about the substances to be dumped gave them little reassurance, for the list resembled the answer to a parliamentary question prepared by a wily civil servant, in that it was true but at the same time said almost nothing. It gave full details of comparatively harmless chemicals, and then such meaningless information as "sludges from wash-pits" and "heavy metals".

The meeting was addressed by county staff and London Brick officials. I was myself involved at the request of the Parish Council. Having heard of all the precautions to be taken, I asked the company's spokesman if he could give an assurance that the tip would never harm the environment of Warboys. I added that there was cause for concern, as I had visited the Bedfordshire Easidispose dump, having been told by villagers living nearby that it made their life a misery. I said that the dump stank, had poor security and so was a danger to trespassing children—would that at Warboys be better? Very honestly, an official of London Brick refused to give me the assurance I sought. He also reproved me severely, saying that he was surprised that someone of my standing had not approached his company so as to be shown what really went on in its dump. This brought the house down.

For three hours the villagers questioned the officials and the company's representatives. Although the answers were frank, and answered many of the specific worries, the audience remained hostile. When the Chairman of the Parish Council put the matter to the vote, not one single citizen supported the motion that they were satisfied with what they had heard. They all agreed to continue their opposition to the establishment of the dump.

There are lessons to be learned from this affair. We all want to get rid of our waste—but only in some one else's parish. Are we doing enough to reduce the problem, and should we be recycling more materials even when this does not seem to be economic? The main lesson, however, is that the ordinary people *are* concerned about some factors in their environment. If those of us who have been involved with the less popular topics such as old buildings and wildlife can show that we are equally concerned with mundane issues like refuse dumps, then we may be able to recruit a much wider section of the population into the conservation movement. We need them if we are to preserve our, and their, environment.

correspondence

Stantec Zebra

SIR,—May we venture to answer your question (October 16, page 544) regarding the present whereabouts of the Stantec Zebra? It is alive, well and working unconscionably hard somewhere approximately 350 miles north of St Albans.

The Computer Board has little reason for complacency as regards the implementation of the Flowers report at Edinburgh Regional Computing Centre (ERCC). Subsequent to the return of a rented IBM 370/158, the centre finds itself without effective access to a major batch processing facility, with concomitant serious consequences for teaching and research at the Universities concerned (Edinburgh, Glasgow and Strathclyde).

The expensive and wasteful débâcle ensuing from totally inadequate attempts by the Computer Board to provide comparable facilities on an IBM 370/168 situated at Newcastle University defies comprehension.

Yours faithfully,

D. WHITE P. MALLISON

Mosquitoes

SIR,—Though not directly connected with the Research Unit on Genetic Control of Mosquitoes in New Delhi, I have followed closely the progress of its research work and the recent unfortunate controversy which surrounded it. I would like to comment briefly on some of the points raised in the letter (September 18) by Mr C. Raghavan and Dr K. S. Jayaraman of the Press Trust of India on the subject of the research unit:

- The release strategy, as set out in the unit's protocol for the planned experiment in the town of Sonepat, was to adjust the numbers of sterile mosquitoes to be released in relation to the number of wild mosquitoes currently emerging in the town, so that any females unavoidably released would constitute only a small minority of the total female population. The journalists' mention of the release of "at least 2,000 females a day" makes the unwarranted assumption that the unit's maximum possible output of 400,000 males a day would have been required in this experiment. In reality, during the first week of the experiment 35,000 sterile males were scheduled for release daily and these would have been unavoidably accompanied by about 90 females.
- The releases in Sonepat would have been from a grid of over 500 release points in the town. All mosquitoes for release were to have been marked with the same colour. Therefore, among the samples of mosquitoes recaptured there would have been no way of knowing from which of the release points or which day's release they originated. Can the journalists seriously suggest that a specialist in mosquito ecology could 'extrapolate' such data to give information on the dispersal pattern of female mosquitoes which would be of use to someone interested in biological warfare?
- It is typical of the journalists' method of argument that in support of grave allegations against the work of the WHO on mosquitoes in India, they produce an unsubstantiated allegation about the work of the FAO on sugar in Cuba.
- The journalists refer to "bird migration studies supoprted by the GCMU [*sic*] and the US Army". In fact the research unit in Delhi had no connection whatsoever with the bird migration study.
- The Assessment of the National Filaria Control Programme (India) 1961–1970 (C. G. Pandit, Indian Council of Medical Research, 1971), recommended a dual strategy based on vector control and drug treatment, contrary to the journalists' statement that exclusive reliance on drugs was advocated. The research at the Filaria laboratories of the Indian National Institute of Communicable Diseases reflects this dual strategy.
- The journalists have missed the point about the conclusion that can be drawn from the history of the eradiction of *Aedes aegypti*, but not other *Aedes* species, from Poona. It has never been suggested that this disproves the existence of a degree of cross immunity between dengue antibodies and yellow fever virus. What it does provide is a practical demonstration that if *A. aegypti* (the vector of urban yellow fever) is removed from an Indian town, this does not cause the appearance of yellow fever, contrary to the fears expressed by the journalists about the consequences of the unit's planned experiment in the town of Sonepat.
- I am surprised by the journalists' opinion that research on "sophisticated technologies" should be restricted to the developed countries, as this runs directly counter to the commonly expressed view that the developing countries require more home-produced technology which has been tested for its feasibility and developed in relation to the actual field conditions in which its application is required. Fortunately the journalists' attitude is not widely shared, and the recent successful genetic control of an *Anopheles albimanus* population in El Salvador (Lofgren, C. S., *et al., Am. J. trop. Med. Hyg.*, **23**, 288–297; 1974) suggests that these techniques may provide a practical weapon in the struggle against malaria and other vector-borne diseases on a much shorter time scale than that suggested by the journalists.

Yours faithfully,

R. J. WOOD

MR GLADSTONE AT GREENWICH

WE may surely regard it as a hopeful sign of progress that a whole page of the *Times*, as well as of other daily papers, of last Friday was practically devoted to the discussion of matters connected with Science and Art. When we find the daily papers giving so great prominence to these subjects, and when men of such position and mark as Prince Leopold, Mr Gladstone, and the Lord Chief Justice, take what is evidently a genuine interest in the progress of science and art education among the lower classes, it seems quite safe to infer that this movement has at last taken a prominent and important place in the everyday life of the country.

Prince Leopold, in his address at Oxford, showed that he had taken some pains to become acquainted with the latest statistics of the Science and Art classes. The discrepancy between Prince Leopold's statistics and those of Mr Gladstone has been commented upon in the *Times*. At the same time it is gratifying that a man like Mr Gladstone should think it worth his while to take an interest in the matter at all, but when he does determine to think about it, the least he can do is to inform himself correctly as to statistics.

news and views

Chromosomal aberrations as tests for mutagenicity

from John R. K. Savage

THE very obvious structural changes which can be induced in chromosomes, and the relative simplicity of the cytological methods which render them observable have made 'chromosomal aberrations' a popular criterion for the evaluation of potential environmental hazards.

Recent developments of staining methods to detect sister chromatid exchanges, SCE (a reciprocal exchange of segments at homologous loci between the two chromatids that comprise the metaphase chromosome arm) have now added another group of structural changes, the induction of which may be utilised as a screening test for mutagens and carcinogens. Results with a wide range of agents reported by Perry and Evans in this issue of *Nature* (page 121) indicate that the test is more sensitive, quicker and easier to use than those employing conventional aberrations. It may also prove to be more relevant since SCE are produced during the DNA synthesis phase, a time when it is thought that most mutations are fixed or established (Auerbach and Kilbey, *A. Rev. Genet.*, **5**, 163–218; 1971).

Perry and Evan's study of SCE illustrates a number of areas where there is a need for caution if the occurrence of induced aberrations is to be used as an indicator of genetic damage.

Of first importance is understanding the nature and mode of action of the agent used to produce aberrations. The properties of the substances used by Perry and Evans covered a wide spectrum. Some had a short half-life giving an acute dose, others were continuously active throughout the treatment period, and one other (cyclophosphamide), because it requires metabolic processes to convert it to an active mutagen, is ineffective *in vitro*. Such information is vital for designing the experimental test.

The need for parallel *in vivo* tests is indicated, not only because of metabolic activation but because the body also has considerable powers of detoxification (Williams, *Detoxication mechanisms*, Chapman Hall, London; 1959). It is possible to expose chromosomes *in vitro* to substances in a form, concentration and *p*H which would be impossible *in vivo*. Moreover a range of different cell systems is needed. Inferences on the mutagenicity of maleic hydrazide based solely on work with plant cells would have been most misleading.

Second, there is a need to appreciate the time of action of the agent in relation to the cell cycle. The majority of chemical substances which produce aberrations, although probably able to induce lesions at all stages of the cycle, require that the cell pass through one or more DNA replication phases in order to allow the lesions to mature into structural chromosome changes. At the same time, these substances invariably cause considerable dose-dependent perturbations in, and delay of passage through, the cycle. Factors such as these will determine how soon after treatment and with what frequencies aberrations will be observed in the test cells. Mitotic perturbation can lead to the simultaneous presence of cells in first, second and even third mitosis after treatment, at the time of sampling, and it may not always be possible to distinguish between them (particularly in the presence of a persistent mutagen) or to assess the effects of cell selection and secondary (derived) aberrations. It is clear that no one 'standardised' experimental design will serve for all mutagenic agents.

Undoubtedly the biggest problem encountered in aberration work is that of quantitation. Given accurate classification and recording of aberration types, can an interpretable dose-response curve be constructed?

On the one hand there is the difficulty of determining the effective 'dose' received by the vital targets in the cell. This may or may not bear a simple relationship to the molar concentration added to the environment of the cells, for it is conditioned by such things as the nature of the agent, the form in which it is supplied, its mode of uptake by the cell, and the density and mitotic status of the test cell populations. If the agent is unstable, the difficulties are enhanced.

On the other hand, there must be some unique quantity or 'yield' to set against dose. Different yields in different cell cycle compartments (see Fig. 2 of Perry and Evans) alert one to the fact that sensitivity to the agent may change as the cell progresses towards mitosis. In passing it should be noted that such changes are not the same for all types of aberrations. Since the cells of a population do not progress at a uniform rate through the cycle, it follows that samples of metaphases, examined at different times after an agent is introduced, comprise mixtures of cells with differing sensitivities and a corresponding variation in observed mean yield is to be expected. The profile of the variation of yield with time of sampling is influenced by many factors, in particular mitotic delay and perturbation (Savage and Papworth, *J. theor. Biol.*, **38**, 17–38; 1973). All known aberration-inducing agents perturb the mitotic cycle, the degree of perturbation differing with dose.

In these circumstances, a unique yield for a given dose does not exist, so that a dose response curve can take a variety of shapes depending on the sampling methods and times used. A great deal more detailed mathematical work on the kinetics of disturbed cell populations is required before any significance can be attached to the form of such curves.

A fact often overlooked when structural aberrations are used as a test system is the very poor resolution they afford in molecular terms. It is all too easy in discussion to couple molecular damage (such as DNA strand breakage or cross-linkage) and observed chromosomal changes, forgetting size differences of many orders of magnitude. Using the new chromosome banding techniques, the loss of a chromatid band (or a major part of it) is about the limit of aberration detection with light microscopy. The Paris Conference 1971, banding norm (*Birth defects*, **VIII**, **7**, National Foundation, New York) has 1,200 chromatid bands in the diploid human female karyotype. If we give equal weight to each band and distribute the 5.8 pg of DNA (Abrahamson *et al.*, *Nature new Biol.*, **245**, 460–462; 1973) uniformly between them, then each band contains 1.61×10^6 nm or 4.73×10^6 nucleotide pairs (a scale model in cotton thread would require ~ 200 m). Thus many significant structural changes could take place within a band and remain wholly undetected by visual means. Equivalence of visible 'breaks' and molecular lesions is therefore of very doubtful value. The rationale for using aberrations is based on the premise, probably valid, that if a substance induces visible change (much of which is lethal to the cell that carries it) it will also induce invisible change having a high probability of transmission and of genetic consequence. Absence of visible changes however does not imply that there are no invisible ones.

Finally, it is worth considering the nature of SCE in relation to conventional aberrations. The former are all reciprocal and symmetrical (that is, they do not give rise to dicentric chromatids and acentric fragments) complete (no loose 'ends') and, within the resolution limits discussed above, the exchange is confined to homologous loci. This is true also of the occasional chromatid interchanges ('quadriradials') found in Blooms syndrome where SCE is much elevated (Chaganti *et al., Proc. natn, Acad. Sci. U.S.A.*, **71**, 4508–4512; 1974). By contrast, conventional chromatid aberrations, whether produced by chemicals or radiation, are frequently asymmetrical, often incomplete and certainly not confined to homologous loci either within or between chromatids (Savage *et al.*, *Chromosomes Today*, **4**, 267–276; 1973).

That SCEs constitute a highly sensitive test, and that agents differ in their ability to induce them is now established beyond reasonable doubt, but in the light of the above differences it would seem unwise to substitute them completely for tests using conventional aberrations until more is understood of their relative genetic significance. Both would seem to be necessary at present.

The observations that with certain treatments, chromosomes may be 'shattered' into small discrete segments (Lovelace, *Genetics*, **38**, 675–676; 1953), that chromosomes precociously condensed in S phase appear to be fragmented (Johnson and Rao, *Nature*, **226**, 717–772; 1970) and the increasing evidence that DNA/protein subunits of uniform size exist in eukaryotic chromosomes (McGhee *et al. Chromosoma*, **52**, 189–205; 1975) lead one to speculate on the doctrine of chromosomal integrity during interphase. Might it be that enhanced SCE implies some interference with a mechanism which links chromosomal subunits? Further studies of these aberrations may throw some new light on the vexing question of chromosome structure and organisation. ☐

Organising neural development

by Miranda Robertson

In the experiments of Chung and Cooke, reported on p. 126 of this issue, two lines of enquiry converge on the optic tectum of *Xenopus*, the African clawed toad. The consequence is that the classical embryological concept of specialised organising regions in development can for the first time be brought to bear directly on the specific question of how ordered neuronal connections are set up in the central nervous system.

Embryonic organisers, according to Spemann, who developed the concept in the early years of this century, are specialised regions which control the morphogenesis and differentiation of the tissues immediately surrounding them. The classical organiser has recently undergone a renaissance in the light, in particular, of the positional information theory due to Lewis Wolpert, and it now emerges as the source of a morphogenetic signal providing information on the relative positions of the cells in the developing field. At the earliest stages of development, the entire embryo is a single field within which the positions of cells are defined by one organiser. According to positional information theory, the subsequent development of the embryo depends on its interpretation of the positional signal. As part of the process of differentiation, the cell acquires a permanent positional label: if it is moved after that stage, it will differentiate in a manner appropriate to its original position.

There is however a stage before the cell's positional label becomes permanent during which the tissue as a whole retains the ability to regulate. If some of the cells are removed at that stage, the remainder adjust to form a complete tissue (or at very early stages, a complete embryo).

It is within this framework that neurobiologists have been attempting to understand the development of the amphibian retino-tectal projection. It has been known since Sperry's classical demonstration in the early 1940s that rotation of an amphibian's eye after section of the optic nerve is followed by the re-establishment of optic connections in the tectum in precisely the same order as before, so that the unfortunate amphibian's visual world is rotated by the same number of degrees as the eye, as his misdirected reflexes bear witness. More recent experiments have done much to explain when and how the retinal cells acquire the information that enables them to reconnect in this invariant way.

The principle of these experiments is to change the position or the orientation of the eye at various stages of embryonic development and to use the retino-tectal map of the adult (mapped electrophysiologically) to assay the effects of the operation. Thus by rotating the eyes of *Xenopus* larvae at different stages, Marcus Jacobson (*Devl Biol*, **17**, 202; 1968) made the important discovery that the cells acquire fixed positional labels along orthogonal axes which are specified at slightly different stages of development. The antero-posterior axis is irrevocably determined by stage 29; the medio-lateral axis a little later at stage 30 or 31.

More recently, Jacobson and Hunt have found evidence (*Proc. natn. Acad. Sci., U.S.A.*, **20**, 507; 1973) that the information for specifying these coordinates derives from a positional signal operating over the entire animal. They have transplanted eyes to the animals' flanks until after the critical stages and then replaced them in the orbit, to show that the retino-tectal map is normal provided that the orientation of the eye was unchanged with respect to the major axis of the animal during its sojourn in the flank. These results conform to modern theory in the sense that the positional signal apparently conveys only general spatial information and differentiation depends on the cell's interpretation of it.

But how specific is that interpretation? Sperry originally postulated two sets of precisely matching chemical labels in retinal and tectal cells. The experiments of Michael Gaze and his collaborators over the past few years however have shown that if such labels exist at all they must remain labile. The most compelling recent evidence is based on the geometry of retinal and tectal growth. The retina grows in concentric rings, whereas the tectum extends backwards from its anterior lateral pole. In spite of this disparity in the geometry of growth at the two surfaces, the orderly array of neural connections is maintained throughout the different stages of larval development (Gaze *et al., Proc. R. Soc., Lond*, **B185**, 301; 1974). Gaze and his colleagues suggested on the basis of their observations that the connections continually shift during development, and their suggestion has now been confirmed (Chung *et al*, *Proc. R. Soc.*

Lond., **B187,** 449; 1974).

Clearly there is no unique cell-to-cell matching, and Chung promulgates the view (*Cell*, **3,** 201; 1974)—credited to Lettvin—that what the retinal cells possess is information on their position relative to each other. If that is rigorously preserved, all that is needed at the tectum is an axial polarity to orient the entire array of retinal fibres.

It is the development of that axial polarity that Chung and Cooke have now subjected to experimental scrutiny. The aim of the experiments was to rotate the tectum at different stages of embryonic development and by later mapping the retinal projection, to determine the stage at which its axial polarity became fixed—in a manner precisely analogous to Jacobson's experiments on rotation of the retina.

The operation is technically very difficult because of the size and fragility of the embryonic brain and because at the stage at which most of the operations were performed (21-24) the different brain regions are determined but not yet anatomically distinct. The rotated tissue in each case was of the order of 15 cells square, and in the light of later anatomical analysis, seems sometimes to have included part or all of the adjoining diencephalon, and/or to have excluded part of the tectum.

Anatomically, therefore, the consequences of the operation varied considerably. Because the brain regions at this stage are determined but not yet differentiated, disturbed fragments of diencephalic or tectal tissue regulated to produce complete structures, giving rise to duplicated diencephalons or tecta, or both, at various positions depending on the exact origin and extent of the rotated tissue.

The effect of the anatomical chaos upon the retino-tectal map however turned out to be strictly independent of the orientation or morphology of the tectal tissue itself. The electrophysiological results clearly showed that the axial polarity of the map was determined by the diencephalon. Where the diencephalon was in its normal position anterior to the tectum, the map was normal; where it was transposed so that the tectum was anterior to the diencephalon, the map was reversed. In one case, where a tectum was wedged between two diencephalons, two maps with opposite polarities were recorded, one starting from each tectal edge. Morphological aberrations were ignored by incoming optic fibres. In an animal in which two tecta had developed side by side, the optic nerve entered aberrantly between the tecta but nonetheless spread out over the surfaces of both to give a normally ordered and polarised map.

Chung and Cooke infer from these results that the diencephalon acts as an organiser controlling the axial polarity of the retino-tectal projection, and preliminary results from grafts of diencephalic tissue alone seem to support this conclusion. They also raise the question of whether the tectal cells ever acquire permanent positional labels.

But the results raise numerous other important questions which are now accessible to experimental investigation. One of the most fundamental concerns the nature of the diencephalic signal. Morphogenetic signals have so far proved uniformly elusive, but until now, neurologists have not known even where to look for them. A further fascinating question is whether it is the same signal that first determines the morphological polarity of the embryo and later provides the axial polarity that guides the optic fibres. The morphological determination of the brain, the determination of axial polarity in the retina, and the determination of the axial polarity of the tectal map are all clearly separated in time.

But the two known organising regions in *Xenopus* are very close neighbours in space. The diencephalon develops from a region overlying the blastopore lip, which is the classical organiser for the early stages of development.

Could the classical and diencephalic organisers control all three developmental processes with the same signal, interpreted by the cells in different ways at different times? The only evidence so far for temporal changes in the interpretation of an organising signal comes from work on the cellular slime mould (Rubin *et al.*, *J. Embryol. exp Morph.*, **33,** 227; 1975), which has the heuristic disadvantage that it is not an embryo but the unique advantage of possessing a chemically identified morphogenetic signal. The identification of an organising region in the amphibian brain offers the opportunity of investigating this question in the developing nervous system of a vertebrate. □

Glassy polyethylene

from P. D. Calvert

In principle any crystalline material can be converted into a disordered glassy solid if it is cooled sufficiently rapidly from the molten state. For some time it has seemed that polyethylene crystallised too quickly for the glassy state to be reached even by splat cooling techniques. But recently Hendra and co-workers have reported the preparation of glassy polyethylene simply by dropping a foil-covered film of polyethylene at its melting point into liquid nitrogen (*J. Polym. Sci. Lett.*, **13,** 365; 1975). The infrared spectrum shows it to be amorphous at 120 K and crystalline after warming to 180 K. Other workers must apparently have allowed their samples to warm up before studying them.

There is no shortage of polymers which can be produced in both crystalline and glassy states but polyethylene is by far the most studied synthetic polymer and there is already controversy over its glass transition temperature. As normally prepared polyethylene is semicrystalline containing 30–70% amorphous material dispersed between small crystallites. The glass transition temperature of this amorphous phase has been claimed to be 125, 193 or 240 K. In a 1973 review (*Macromolecules*, **6,** 288) Boyer argued strongly for 193 K. Hendra's experiments show crystallisation occurring above $\sim$ 170 K suggesting that the glass transition must be below this.

At the Shrivenham meeting of the polymer physics group of the Institute of Physics, Hendra discussed some even more controversial results. Using a peak in the Raman spectrum at about $20\,\mathrm{cm}^{-1}$, which is a longitudinal acoustic mode of the whole chain segment within a crystal, they could measure crystal thicknesses. Crystals which form at 160–180 K have a thickness of about 170 Å parallel to the chain. This value is similar to that found in high temperature crystallisation. Since chain motion must be very restricted so close to the glass transition this result suggests that large scale untangling is not necessary for crystallisation and so throws doubt on the chain-folded crystallisation concept which is the basis of most present theories of crystallisation.

Worse still, they found that the crystal thickness formed on warming the glass depended on the temperature at which the polyethylene was melted before quenching to the glassy state. Melting at 400 °C gave rise to 155 Å crystals; at 160 °C the crystals formed were 180 Å thick. This is heretical in that liquids are not thought to contain any significant structures which could be quenched in and affect subsequent crystallisation. The results might be attributed to degradation of the polymer or destruction of nucleating particles but melting at 160 °C subsequent to melting at 400 °C again produces 180 Å crystals so the effect is reversible.

Thymus-dependent lymphocytes

from P. B. Medawar and Elizabeth Simpson

Under the patronage of the Rockefeller Foundation a conference was held at the Villa Serbelloni, Bellagio, Italy, from September 1–6, to consider the functional taxonomy of populations of thymus-derived lymphocytes, and by implication their role in the functional integration of the immune system.

THE subjects under discussion included 'T cell differentiation and subsets of T cells,' 'What do T cells see?' 'Ir control and cell interactions,' 'Suppressor T cells,' 'Idiotypes and networks,' and 'The IXth linkage group of genes in the mouse.'

Although the identification of Ly differentiation surface markers for peripheral T cells (Boyse *et al.*, *Proc. R. Soc.*, **B170**, 175; 1968; Cantor and Boyse, *J. exp. Med.*, **141**, 1376; 1975) was seen as a significant step forward in characterising functionally distinct subsets of T cells, the limited availability of anti-Ly sera is an obstacle to the general application of a system of classification based solely on such surface markers. On the basis of the published information referred to above, and unpublished information provided by several participants (E. Boyse, H. Cantor, P. Beverley, D. Schendel and K. Rajewsky) a tentative classification table was nonetheless drawn up taking into consideration the characteristics of three basic peripheral T cell types, T helpers (T_H), T cytotoxic cells and T suppressor cells ($T_{C,S}$) and early or immature T cells (T_E). The scheme (Table 1) attempts to bring together a number of older observations with the new data obtained from experiments with anti-Ly sera.

In answer to 'What do T cells see?' it is possible that T cells are triggered by antigen associated with molecules of the major histocompatibility complex (H molecules). Three pieces of evidence are particularly relevant.

(1) In some systems cytotoxic T cells seem to recognise a neoantigen formed by association between hapten-like determinants and H-2K and H-2D molecules (see Lennox, *Nature*, **256**, 7; 1975).

(2) Ly 1$^+$ helper T cells (which are active in both antibody and cytotoxic responses) probably react to Ia determinants, coded by the I region of the major histocompatibility complex, while Ly 2, 3$^+$ killer cells respond mainly to H-2K (Lipsky and Rosenthal, *J exp. Med.*, **141**, 138; 1975; Cantor and Boyse, *J. exp Med.*, **141**, 1390; 1975).

(3) Several studies suggest that most, if not all T cells have receptors for H antigens (for example, Ford *et al*, *J. exp. Med.*, **141**, 681; 1975).

For triggering to occur, therefore, the T cell receptor may bind to a complex formed by H molecules and specific antigen. Either, one receptor site may bind the neoantigen, or two separate binding sites (on the same or different molecules) may recognise the self H antigen and the foreign haptenic determinant. More specifically it may be that antigen associated with H-2K/H-2D molecules would preferentially trigger an Ly-2,3$^+$ killer or suppressor cell response, while antigens linked to Ia molecules would preferentially stimulate Ly-1$^+$ helper activity. This model implies that the primary function of T cells is to "screen" self H molecules for the presence of non-self determinants. Further work is needed to isolate the T cell receptor and/or the proposed antigen–H complexes before this hypothesis can be rigorously tested.

Table 1 T cell subsets

Character	T_H	Subset* $T_{C,S}$	T_E
Ly phenotype	1	2,3	1,2,3
Ontogeny early	+		+
Primary CMI reaction (to H-2)	"LD" (I region)	"SD" (K,D regions)	
Cytotoxic cells:			
Precursors		+	
Effectors		+	
T/T help			
Non-specific (MLR)	+		
T suppression (probably T/T):			
Specific		+†	
Non-specific			+ ?
T/B help: specific	+		
Ia phenotype		+ ?	
Histamine receptor		+	
ATx sensitivity			+

+, Character present.
+ ?, Character probably present.
*It is not implied that all cells in a given subset exhibit all the characters listed.
†Ly 2 positive

The way in which I region immune response genes exert their control over cell–cell interactions in immune responses, and hence over both T and B cell responses to specific antigen, is still a matter for debate. There are at least three interactions which must be considered—macrophage/T, T/T and T/B. A requirement for I region identity for these interactions has been shown in some systems (Katz *et al.*, *Proc. natn Acad. Sci. U.S.A.*, **70**, 2624; 1973) but not in others (McDevitt *et al.*, in *Genes, Receptors, Signals*, 597, Academic Press, 1974; Heber-Katz and Wilson, *J. exp. Med.*, **142**, 928; 1975; von Boehmer *et al*, *J exp. Med.*, **142**, 989; 1975). Genetic analysis of the antibody response of different strains to several antigens, Thy 1, LDH, GLΦ and TGAL has demonstrated complementation groups, indicating that at least two genes are involved (Zaleski *et al.*, *Trans. Proc.*, **5**, 201; 1973; Melchers and Rajewsky, *Eur. J. Immun.*, in the press; Dorf *et al.*, *J. exp Med.*, **141**, 1459; 1975; Rude and Gunther, *Progress in Immunology II*, **2**, 223; 1974; Munro and Taussig, *Nature*, **256**, 103; 1975). For LDH and GLΦ the two genes are encoded in different I subregions of the major histocompatibility complex, while for TGAL both genes may be in the IA subregion. In the response to GLΦ there is some evidence that both genes are expressed on B cells, whereas for TGAL there is evidence that one gene is expressed by B cells (± macrophages) and the other on T cells. The simplest view would be that most T cell interactions with other lymphocytes and macrophages are mediated by various proteins bearing different Ia specificities all of which are under Ir control.

The ways in which T cell suppression controls immune responses are still unclear, but recent work has clarified at least some pathways. It has been suggested that an antigen may have different determinants for initiating help and suppression, but that these determinants must be linked on the same molecule.

One very striking finding has been that in several quite different systems, for example antigen-specific suppression, allotype suppression and con A induced suppression (Feldmann *et al.*,

Stanley rides again

by Mary Lindley

BIOLOGISTS who joined the recent Zaire River expedition brought back a fine collection of flora and fauna, even if at times they may have felt that the price was rather high. In spite of bothersome details such as malaria, amoebic dysentery, fearsome rapids and mysterious footprints, the report delivered by three members of the expedition to a meeting of the Linnean Society on October 16 indicated a mission largely successfully accomplished.

Conditions were considerably better for the scientists, soldiers and other experts who set out under the auspices of the Scientific Exploration Society, in October 1974, than they had been 100 years before for Sir Henry Stanley and his followers who traced the course of the Congo, as the 2,718-mile long river was then called. This time, as Major J. Blashford-Snell reported, there were no hostile war canoes to face, and the inflatable boats used by the expedition were more serviceable than Stanley's Lady Alice, which had to be carried overland whenever rapids were approached. Stanley had no scientists in his party, but this time there were 50, with varied medical, anthropological, geological, zoological and botanical interests. The two latter groups were represented at the meeting by K. A. Joysey (University of Cambridge) and H. W. Woolhouse (University of Leeds), respectively.

Joysey and his colleague, A. Friday, were concerned particularly to look for specimens of the West African otter shrew (*Potamogale velox*), a large and vicious insectivore that lives in muddy water and is apparently active only at night. After a rendezvous with local pigmies, an otter shrew was eventually found, but proved elusive. The natives later presented the specimen, freshly killed, to the two zoologists who quickly removed the blood needed for serotaxonomic studies. The body is now in the Museum of Zoology at Cambridge.

Other aquatic animals proved less elusive, with local markets yielding a good catch of lung fish (*Protopterus*), elephant fish (various genera of the family Mormyridae) and paddle fish (*Polypterus*) needed for protein sequence studies of muscle aldolase. Throughout the four months of the expedition a party was also collecting fish—from the lakes, tributaries and headwaters—for the British Museum (Natural History). Other ichthyologically inclined members of the expedition collected parasites, bile salts (for an evolutionary study) or fossil specimens. But the entomologists acquired the largest collection. They took home 4,000 Lepidoptera, constituting 800 species, of which a proportion is considered to be undescribed. Experts at the British Museum (Natural History) are now working on these specimens, some of which will eventually be returned to the Government of Zaire. In the tropical rainforest the canopy level turned out to contain the greatest diversity of insect life, which seems to be quite distinct from the insect flora on the ground.

Throughout their journey, the three botanists on the expedition collected seeds of woody legumes for biochemical analysis of unusual amino acids. In southern Zaire, plant and soil specimens were collected for a study of the distribution of plants in relation to copper outcrops and the zonation of the flora was found to reflect the changing concentration of copper in the soil. A few species were growing in unusually toxic concentrations, with some lichens surviving on 5% copper. The material collected will be used in the search for the physiological basis of copper tolerance.

Data for a study of growth and productivity of *Papyrus*, with the aim of investigating the feasibility of making use of *Papyrus* again, was collected from the Upemba swamp basin, where the British botanists found working conditions none too pleasant. Another botanical project was a study of the frequency and distribution of plants which have the C4 pathway of photosynthesis. The outcome of this study will be reported later.

Nature, in the press; Herzenberg and Cantor, unpublished; Cantor and Pierce, unpublished) suppressor cells have an Ly phenotype (Ly 2,3) different from that of helper cells (Ly 1). They also possibly carry histamine receptors (Eichmann *et al.*, *Eur. J. Immun.*, **5**, 511; 1975) and may be Ia positive (Hammerling and Black, *Tenth Leucocyte Culture conference*, 1975). (See Table 1.) The view that at least some T suppressor cells may exert their effect by interaction with T helper cells rather than directly with B cells (Herzenberg and Cantor, unpublished) is supported by much previous data. This may well be a manifestation of helper and suppressor cells belonging to different subsets of T cells having complementary cell surface structures for interaction.

Recent work on idiotypes has shown that an antigen-specific receptor on T cells involved in help for antibody production and on T cells involved in anti-MHC (major histocompatibility complex) responses shares determinants with the immunoglobulin receptor for that antigen on B cells (Binz and Wigzell, *J. exp. Med.*, **142**, 197; 1975; Eichmann and Rajewsky, *Eur. J. Immun.*, in the press). If this receptor is not cytophilically acquired, this work has important implications concerning the nature of T cell receptors and suggests at least shared expression of a V region gene on both T and B cells, perhaps in association with an H region product (for example Taussig and Munro, *Nature*, **251**, 63; 1974). The fact that the idiotypes of receptors are antigenic and can provoke immune responses (refs above, and Jerne, *Harvey Lecture*, 1975, in the press, Lee *et al.*, *Nature*, **247**, 55; 1974) also opens up the possibility that an immune response to one antigen, once initiated, can provoke another immune response which limits or enhances the first response. This anti-idiotype response may, in turn, give rise to an anti-anti-idiotype response, and so on. This network theory has found favour amongst theorists and the data now accumulating suggest that anti-idiotype responses can occur during an immune response — but there is no good evidence as yet for their having a normal regulatory role.

The MHC plays an important part in cell–cell interactions during the induction of a whole range of cellular and humoral immune responses. In mice the MHC (H-2) is a series of loci mapping in the IXth linkage group (chromosome 17). Several other possibly analogous loci also exist on this chromosome. Of these the T/t region near the centromere has long fascinated developmental biologists because it governs a sequence of distinct steps in embryogenesis. These events are precisely defined by the recessive-lethal *T/t* alleles because each of them halts development at the very point where the functional allele would normally act. The prevailing supposition that morphogenetic processes of this kind must involve genetically programmed sensory devices of the sort implied by terms like "cell–cell recognition" is substantiated by the finding that the T/t genetic system, and at least one functional allele (+^{t12}) determines a distinct antigen (F9) that is expressed selectively on cells in a particular phase of differentiation. There seems to be a reciprocal relationship in the expression of this F9 antigen and the H-2 antigens—F9 in the embryo and H-2 in the adult. The *H-2* region lies close to *T/t* and is frequently tied to it in wild mouse populations by the presumably advantageous suppression of crossing over which is a property of *t* alleles. It is therefore of interest that genes at four loci within a region of some 15 centimorgans on chromosome 17 — *T/t, H-2K, H-2D* and *Tla*—have been shown to specify membrane glycoproteins of similar structure including the incorporation in each of them of a small subunit which is probably β-2-microglobulin. This was the main argument advanced by Artzt and Bennet (*Nature,* **256,** 545; 1975) in support of the hypothesis that this family of four loci are descendants of an ancestral locus that acquired the property of cell surface perception as a condition of metazoan evolution. The immune system can therefore be considered as a special case of adaptive differentiation using as its cornerstones genes which may be reduplications of genes coding for receptors that are important in more primitive cell recognition.

We are grateful to the Wellcome Trust for a contribution to travelling expenses. ☐

Slugs and plants

from Robert M. May

MUCH information about the natural history of plants and animals may be assembled in an orderly framework by noting that the world tends to provide a continuum of environments, ranging from the unpredictable (where evolutionary pressures are for rapid population growth to exploit the transient good times), through to predictable and biologically crowded environments (where evolutionary pressures are to be a good competitor). These notions, which reach back to Darwin, are commonly formalised in terms of the extremes of "r-selection" and "K-selection", respectively (see *Nature,* **257,** 737; 1975).

One application of these ideas is to the phenomenon of succession This phenomenon, whereby untended open space tends to revert to weeds, then shrubs, and eventually to woodland, is familiar to all possessors of suburban lawns. The temporal procession from early succession to late succession and climax is a paradigmatic example of a gradient from r-selection to K-selection. On a small scale, such gradients from r- to K-selection have been documented in populations of dandelions (Gadgil and Solbrig, *Am. Nat.,* **106,** 14–31; 1972), goldenrods (Abrahamson and Gadgil, *Am. Nat.,* **107,** 651–661; 1973) and other wild flowers growing in patches subject to significantly different degrees of disturbance McNaughton (*Am. Nat.,* **109,** 251–261; 1975) has recently supplemented this work with a meticulous study of populations of cattails (*Typha*) in a variety of sites with differing lengths of frost-free growing periods. He shows the relatively unpredictable locations with a short growing season favour r-selected genotypes which have faster development, produce more offspring (seeds), but invest less energy in each offspring (smaller seeds) and put less premium on traits conferring competitive ability, such as height (to shade out other plants).

A somewhat deeper test of the ideas comes from considering the relation between plants and the beasts that eat them, as a function of successional stage. Compared with late successional plants, those in early succession should invest relatively more of their resources in growth (and reproduction), and relatively less in defence against herbivores. This is so, both for the reasons outlined above, and because the patchy and unpredictable distribution associated with early succession itself provides a degree of escape from herbivores. Thus early successional plant species should provide better food sources for generalised herbivores than do later successional and climax plants. Cates and Orians (*Ecology,* **56,** 410–418; 1975) have recently tested this by taking 100 plant species, of three growth forms and from different seral stages, and determining their short-term palatability to two slug species, one native to western Washington (*Ariolimax columbianus*) and one introduced from Europe (*Arion ater*). Palatability of a given test plant was measured as the ratio of test material eaten to control material eaten, in a well-defined laboratory setting. The results showed that early successional annuals were significantly more palatable than early successional perennials, which in turn were significantly more palatable than later successional species. This validation of theoretical expectations was clear cut, in that no correlation was found between palatability and evolutionary association of the herbivores with particular plant species.

Specifically, Cates and Orians define a "palatability index" as the ratio of log (amount of test material eaten) to log (amount of control material eaten). Then for the native slug *Ariolimax,* the average palatability index for early successional annuals and biennials was 0.96, for early successional perennials 0 77, and for later successional and climax plants 0.46. The corresponding figures for the European slug *Arion* were 0.99, 0.69, 0.40.

A more detailed field and laboratory study of one particular slug–plant system has also been carried out by Cates (*Ecology,* **56,** 391–400; 1975). Using wild ginger (*Asarum caudatum*) and again the native slug *A. columbianus,* he showed the plant populations were polymorphic for growth rate, seed production, and palatability to the slug. In habitats where slugs were relatively rare, populations of wild ginger were dominated by individuals allocating more energy to growth rate and seed production, and less to the production of biochemicals that slugs find nasty. Conversely, in habitats where the slugs were abundant, the more K-selected individuals predominated.

Cates and Orians note that slugs are not "representative" generalised herbivores, because they tend to avoid grasses. Nonetheless, the successional trends they have documented march with the results of other studies, and indicate "broad patterns in the ways plants and herbivores have mutually influenced one another's evolution."

Biochemical factors in schizophrenia

from Richard Rodnight

THE paper by A. G. M. Pearson and A. J. Turner in this issue of *Nature* (page 173) bridges two areas of research—transmethylation and folic acid metabolism—both of which have potential significance for studies of the biochemical basis of psychotic behaviour in man. A disturbance of transmethylation has often been proposed as a possible factor in the aetiology of schizophrenia, but until recently there were few clues as to the pathways which might be involved. A possible mechanism came to light with the discovery in 1961 by J Axelrod (*Science,* **134,** 343) of a methyltransferase enzyme in rabbit lung that transfers methyl groups from S-adenosylmethionine (SAM) to the naturally occurring indoleamine tryptamine to form mono- and dimethyltryptamine (DMT). The latter compound has been known for many years to induce in normal subjects a model psychosis when administered parenterally, an observation which evokes the suggestion that some of the typical symptoms of schizophrenia may be due to the aberrant production of endogenous DMT in the affected individuals. There is indeed good evidence now that the body does convert minute fractions of its stores of

The bee language controversy

from John R. Krebs

Karl von Frisch's Nobel Prize winning discovery of the dance language of honeybees is one of the classics of biology. Over many years von Frisch collected evidence to show that when a successful foraging bee returns to the hive it is able to recruit other workers by communicating the precise distance and direction to the food source, encoding this information in the abstract symbolism of a 'dance' performed on the hive surface. The distance is encoded in the speed of dancing and the direction by the orientation of the figure-of-eight dance in relation to gravity. This remarkable feat places honeybees second only to man and perhaps chimpanzees in the use of abstract symbols in transmission of information.

About eight years ago, Adrian Wenner pointed out that two of von Frisch's best known experiments were not as convincing a demonstration of the dance language as most people had thought. In these two studies, known as the 'step' and 'fan' experiments, von Frisch showed that naive recruit bees would go specifically to experimental food dishes indicated by the dances of experienced foragers, and ignore identical nearby control dishes. In the fan experiment the control and experimental dishes were at the same distance from the hive but in different directions, and in the step experiment the dishes were in the same direction but at different distances. Wenner correctly pointed out that not only is the experimental dish in these experiments unique in being the one indicated by the dance, but also it is the one towards which experienced foragers are flying. The recruits could either be using the dance information or simply watching where the foragers go. Wenner eliminated this confounding variable by training equal numbers of foragers from a separate (control) hive to go to each of the control dishes, and he now found that recruits from the experimental hive no longer preferred the dish indicated by the dance. Wenner's conclusion from this and other experiments was that recruits may be stimulated to leave the hive by the dance, but that they normally search for food by smell, using the smell of the dancing foragers as a guide.

Naturally enough, Wenner's results aroused enthusiastic criticism, followed by new experiments supporting von Frisch's story, with further counterclaims by Wenner and his colleagues, culminating in a headline in *Nature* (**241**, 171; 1973) suggesting that von Frisch's data could be explained without recourse to the dance language theory. One valuable consequence of Wenner's criticisms was that people devised more rigorous tests of bee dance communication, and the latest of these studies, by J. L. Gould (*Science*, **189**, 685; 1975) finally shows beyond doubt that bees use the dance information.

In a most beautifully ingenious experiment, Gould exposed recruit bees to conflicting information: the dance indicated one direction, while the foragers that gave the dance flew in another direction. The key to Gould's experiment is the fact that bees can be persuaded to orientate their dance in relation to the Sun or (in the case of Gould's experiment) a bright light instead of gravity. As long as the recruits can also see the Sun or bright light, they automatically 'read' the dance correctly, using the light source instead of gravity as a reference. What Gould did then was to cover the ocelli of the dancing foragers with black paint so that they could not see the artificial Sun (a 650 watt bulb) shining into the hive but could still forage and dance. The returning foragers now oriented their dance with respect to gravity, as usual in a dark hive, but the recruits interpreted the dance as though it were oriented with respect to the bright light. To give an example, suppose the bright light is placed at 60° to the vertical, and a returning forager has just come from a food dish directly in line with the real Sun outside. The forager dances on the vertical surface of the hive, unaware of the bright light, and orientates her dance vertically upwards (which is the gravity-based code for 'towards the Sun') The recruits, however, read the information as '60° from the line of the Sun', and head off in a different direction from the foragers. Recruits always arrived at food dishes in the direction indicated by their interpretation of the dance, and not at the experimental dish used by the foragers. Further, by moving the bright light to different positions in the hive, Gould could get the recruits to go to different feeding dishes—always the one predicted by incorrect reading of the dance

It is also particularly satisfying that Gould was able to show at least one reason why Wenner did not find any effect of the dance on recruits. In the initial part of any dance experiment, a few chosen foragers are trained to fly to a particular dish, this being the dish they indicate to naive recruits in the dance. Wenner used training dishes scented with the same odour as was later used in the experiment, while Gould was careful to change to a new scent on the day of the experiment. If Gould used the same scent for both training and experiment, he got the same results as Wenner: the recruits went to any dish with the same scent as that carried into the hive by foragers. The conflict between the von Frisch and Wenner results is at least partly due to details of experimental design and, as Gould points out, this might well mean that recruit bees use the dance information when they are just starting to exploit a new food source but use scent, as Wenner proposed, when exploiting the same food source at a later stage.

---

indoleamines to N-methylated products with hallucinogenic properties. Traces of both the mono- and dimethylated derivatives of tryptamine and serotonin are excreted in human urine and may occasionally be found in blood; the excretion, moreover, does not seem to be derived from the diet or bacterial action in the bowel. There are also reports, as yet unconfirmed and inadequately documented, that mentally ill patients with the diagnosis of non-affective psychosis tend to excrete more DMT in their urine than do mentally ill patients with other diagnoses or normal subjects. It is, however, uncertain how much, if any, of urinary DMT is derived from tryptamine methylated in the brain. There is no doubt that human lung contains an SAM-dependent methyltransferase which forms DMT from tryptamine, the enzymic basis for the same reaction in mammalian brain is now much less clear than formerly suspected. Earlier reports on the occurrence of an indoleamine methyltransferase in brain using SAM as methyl donor were based on unsatisfactory methods of product identification and the reaction urgently needs reassessing by more precise methods such as gas chromatography and mass spectrometry.

Suspicions that folic acid might be involved in the endogenous formation of hallucinogens in the body arose about 3 years ago when several reports appeared indicating that besides SAM,

N^5-methyltetrahydrofolic acid (5-MTHF) could act as methyl donor for the N-methylation of biogenic amines in the brain; dopamine, apparently yielding its N-methyl derivative epinine, appeared a particularly good substrate but it was also claimed that both tryptamine and serotonin could be N-methylated in this system. Unfortunately product identification in these experiments was no better than in the parallel studies using SAM as donor. The usual procedure has been to incubate a crude mixture of soluble proteins from the tissue under study with radioactive SAM or 5-MTHF in the presence of acceptor substrate and then to extract the labelled products with solvents and fractionate them on one or more TLC systems, comparing migration rates with those of authentic compounds. When the combined method of gas chromatography/mass spectrometry was applied by several workers to the products produced in the 5-MTHF-dependent reaction it became evident that methylation of the side-chain amino groups in the case of either dopamine or the indoleamines does not occur. With dopamine as acceptor the product was shown to be a tetra-hydroisoquinoline alkaloid (Laduron and Leysen, *Biochem. Pharmac.*, **24**, 929; 1975) and with the indoleamines formation of the corresponding tetrahydro-β-carbolines was demonstrated (Wyatt *et al. Science*, **187**, 853; 1975). Further examination of the nature of the reaction showed that it consists essentially of the enzymic formation of a 1-carbon compound from 5-MTHF followed by nonenzymic condensation with amine and cyclisation to give the products mentioned above The 1-carbon unit was shown by Laduron to be formaldehyde, a compound which would be expected to react with aromatic alkylamines by the Pictet-Spengler condensation to give the corresponding cyclic compounds. What then is the mechanism by which formaldehyde is formed enzymically from 5-MTHF? The answer to this question has been given simultaneously by Pearson and Turner (this issue) and R. T. Taylor and M. L. Hanna (*Life Sci.*, **17**, 111–120; 1975). Both groups of workers show that formaldehyde production from 5-MTHF is a result of the activity of the widely distributed enzyme methylenetetrahydrofolate reductase, which is present in crude tissue extracts. This enzyme normally catalyses the NADPH-dependent formation of 5-MTHF from N^5, N^{10}-methylene tetrahydrofolate; in suitable conditions and in the presence of electron acceptors it may act in the reverse direction to yield from 5-MTHF, methylene tetrahydrofolate, which in turn is known readily to disocciate into tetrahydrofolate and formaldehyde. Pearson and Turner have purified the reductase from pig liver by gel filtration and isoelectric focusing and in the process were unable to separate it from the putative dopamine methyltransferase activity. Taylor and Hanna investigated the previously reported stimulation of the enzyme activity by FAD and methylcobalamin (an observation earlier deduced as evidence for an involvement of N^5-MTHF homocysteine methyltransferase in the N-methylation of biogenic amines) and concluded it is a result of the ability of these compounds to act as nonspecific electron acceptors

While these observations tend to discount a role for folic acid in the endogenous formation of N-methylated hallucinogens it is of interest to note that the β-carboline products bear a close structural resemblance to the alkaloids harmine and harmaline, compounds which reputedly possess psychotomimetic properties in man. Moreover a case of "folate-responsive schizophrenia" in an adolescent girl has been described (Freeman *et al.*, *New Engl. J. Med.*, **292**, 491, 1975). This patient presented with many of the typical symptoms of schizophrenia and was found on investigation to have a genetically determined deficiency in the activity of the enzyme 5, 10-methylenetetrahydrofolate reductase. The enzyme defect resulted in a decreased formation of 5-MTHF and in homocystinuria due to inefficient remethylation of homocysteine to methionine The patient's symptoms dramatically improved on administering high doses of folic acid, but reappeared when the therapy was discontinued. It looks as though the complex interrelations of the cerebral metabolism of methionine, folic acid and the cobalamines may remain a fruitful area of research for those workers interested in the role of biological factors in the genesis of the schizophrenic syndrome. ☐

Angular momenta of planets and asteroids

from David W. Hughes

REGULARITIES in the contemporary structure of the Solar System provide clues not only to the primordial conditions in the system, but also to the accretion mechanisms that formed the planets and satellites and to the subsequent collisions that have taken place between these bodies. The Titius-Bode laws (relating planetary and satellite spacings to their place in the numerological sequence) and the fact that the majority of planets and satellites move in prograde, near circular orbits which lie close to the ecliptic plane are two regularities that have been known for a long time. It is also well known that most planets and satellites spin about axes which are perpendicular to the ecliptic. The relationship between the rotational angular momenta of planetary bodies and their masses is a more recent discovery, however, being first noticed by MacDonald (*Space Sci. Rev.*, **2**, 473; 1963).

The angular momentum of a body is simply the product of its angular spin velocity, ω, and moment of inertia, I. (The moment of inertia is given by $I=Mr^2\alpha$ where M is the mass, r the radius and α the gyration constant; α is 0.4 for a solid equidense sphere). Figure 1 is a logarithmic plot of the angular momenta of planets and asteroids as a function of their masses, the line in Fig. 1 having the form

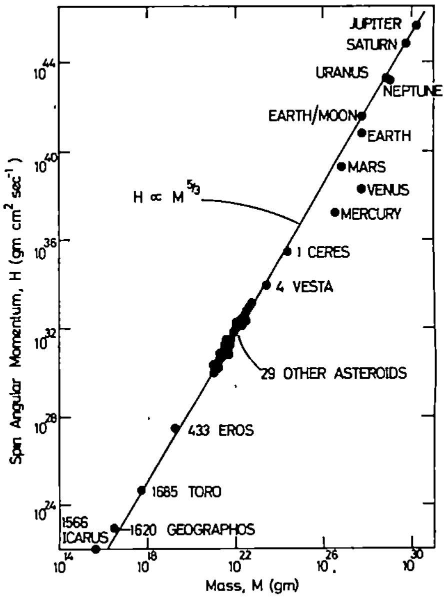

Fig. 1 A logarithmic plot of the spin angular momenta of planets (with the exception of Pluto) and 35 asteroids with well-determined sizes, shapes and rotation rates as a function of their masses (after Fish, *Icarus*, **7**, 251; 1967, Hartmann and Larson, *Icarus*, **7**, 257; 1967 and Burns, *Icarus*, **25**, 545; 1975).

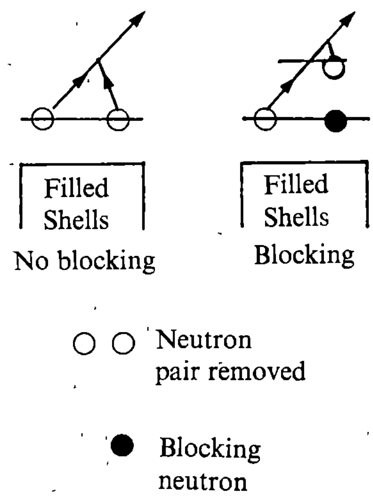
$H=1.47\times10^{-5}M^{5/3}$ where H and M are both in c.g.s. units T, the rotational period, is found by substituting $T=2\pi/\omega$ into the above equation. This

Neutron blocking in alpha-transfer

from P. E. Hodgson

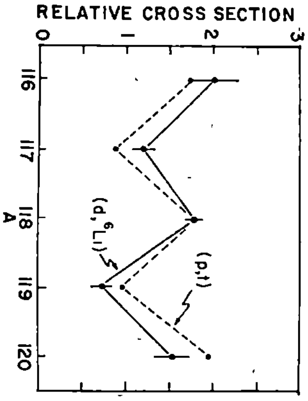
NUCLEAR reactions often give us very direct information about the detailed shell structure of nuclei. This is shown particularly well by the many studies of single-particle states by one-nucleon transfer reactions. In these reactions, a nucleon is either removed from a nucleus or given to it, and study of the angular distribution of the outgoing particles tells us the quantum numbers and the occupation probabilities of the single-particle state involved (*Nature*, **245**, 74; 1973, **249**, 695; 1974).

There are also some reactions in which more than one nucleon is transferred at the same time, and these can sometimes tell us about the nucleons that are not participating directly in the reaction. Such nucleons can get in the way, or 'block', the reaction, thus reducing the probability of its taking place



The first examples of this were found in studies of the (p,t) reaction, which removes two neutrons from the nucleus. In a nucleus with an even number of nucleons both neutrons can be removed from the same single-particle state, whereas if there is an odd number of neutrons it may be necessary to take the neutrons from different states. This latter process is more difficult, and the cross section for the reaction is reduced by a factor of about two. In this way a neutron that does not participate directly in the reaction nevertheless makes its presence felt and thus gives us information about nuclear structure (Fleming, Blann and Fulbright, *Nucl. Phys.*, **A163**, 401; 1971).

This blocking effect has now been observed in alpha-transfer reactions as well. Becchetti and Jänecke (*Phys. Rev. Lett.*, **35**, 268; 1975) have measured the cross sections of several (d,^{6}Li) reactions on even and odd isotopes of tin. The reactions on the even isotopes can just remove the two neutrons from one single particle state and the two protons from another, but the reactions on the odd isotopes have to take the neutrons from different states. This is more difficult, and as shown in the figure the corresponding cross sections are again reduced by a factor of about two.



Comparison between the relative cross sections of (p,t) and (d,^{6}Li) reactions as a function of A for some tin isotopes.

This blocking in alpha-transfer is very similar to the same effect in (p,t) reactions, and suggests that the mechanism is essentially the same, with the two transferred protons acting simply as spectators. The regularity of the reduction suggests that it is the $3S_{1/2}$ state that has an odd nucleon in the odd isotopes, and this is expected from the simple shell model.

The spectroscopic factors obtained by analysing the data with the distorted wave theory show a similar reduction for the odd isotopes, confirming that it is not simply due to the differences in binding energies and Q-values, but is a real nuclear structure effect.

---

gives $T=4.3\times10^5\alpha r^2M^{-\frac{1}{2}}$. If the body is assumed to have a constant density, ρ, throughout (that is, $M=1.33\ \pi r^3\rho$) and an α of 0.4 then $T=6.59\times10^4\rho^{-\frac{1}{2}}$, which, when the assumption is made that all Solar System bodies have the same density and no central mass concentration, confirms Alfvén's findings (*Icarus*, **3**, 52; 1964) that all planets and asteroids have approximately the same period of rotation. Using a density of 3 g cm^{-3} this period comes to 8.8 h.

It can be seen from Fig. 1 that Mercury and Venus have considerably lower angular momenta than predicted by the linear relationship. This is due to tidal interactions between these planets and the Sun. The high rate of spin deceleration suffered by Venus indicates that the solid dissipation inside the planet is considerable. This is only possible if large regions in the interior of Venus are near their melting point thus enabling creep, elastoviscosity and 'direct' viscous interactions to play their part in dissipating energy. Combining the angular momentum of the spinning Earth and the orbital angular momentum of the Moon gives a point on the line in Fig. 1 indicating that the angular momentum of the Earth–Moon system has not changed much during the history of the Solar System. All that has happened is that the Moon has moved further away, and the Earth now spins more slowly.

In a recent paper in *Icarus* (**25**, 545; 1975) Burns doubles the number of asteroid points used in Fig. 1. Accurate sizes based on the radiometry and polarimetry work of Chapman, Morrison and Zellner (*Icarus*, **25**, 104; 1975) are used together with an attempt to include for the first time the effect of an asteroid's non-sphericity. The brightness of asteroids vary with periods scattered around 9 h. These brightness variations, which in some instances range up to two magnitudes but are more typically 0.2 magnitude, are primarily caused by the asteroid having an irregular shape and have been used by Burns to deduce their shape. As the asteroids usually rotate about their principal axes of maximum moment of inertia they contain more angular momentum per unit mass than a spherical body. The effect of inter-asteroid collisions should make the smallest asteroids spin faster and be more irregular. It can be seen in Fig. 1 that 1566 Icarus and 1620 Geographos both lie above the straight line, indicating that they are spinning faster than expected.

Why is the spin period around 9 h? It seems that the accretion processes which formed the planets and asteroids become less and less efficient as these bodies get nearer and nearer to their rotational stability limit. This limit occurs when the rotational surface velocity of the body is equal to its escape velocity (that is when $T\approx3.3\rho^{-\frac{1}{2}}$ h, a rotational period of ~ 2 h for a body of density 3 g cm^{-3}). A conclusion might be that bodies cannot accrete if they spin faster than about one third the rotational stability limit.

Deviations of the spin axes from the normal to the ecliptic are probably due to the statistical fluctuations in the final accumulation of any planet, in other words Uranus' unusual 98° obliquity could be produced by the angular momenta brought in by the last few accreting planetismals. This statistical fluctuation in the accretion process also causes the scatter in the asteroid data.

Two other questions are of interest. First, do these collision-induced spin rates in asteroids ever become so rapid that the surface layers are not gravitationally bound? Excessive spin rates could sweep away any regolith and leave a clean surface. Burns concludes that this does not happen. Even in the case of 1566 Icarus, the smallest and fastest spinning asteroid of known rotation and shape, and 321 Florentina the second most rapid rotator, their densities have to be less than 2.8 and 2.3 g cm^{-3} respectively for this to occur. As asteroids seem to fall into two main compositional groups, however, (Chapman *et al.*, *Icarus*, **25**, 104; 1975) similar to carbonaceous chondrite meteorite (Type I has $\rho=2.5$ g cm^{-3}, Type II has $\rho=2.9$ g cm^{-3}) and to stony-iron meteorites ($\rho=5.0$ g cm^{-3}) things are getting pretty close.

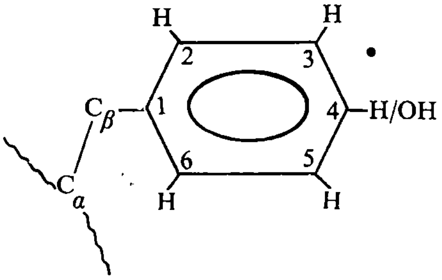
Second, are the spin rates fast enough to cause internal tensile stresses which over long periods of time, split the asteroids apart. Burns again concludes that the answer is no and that if forces are attractive on the surface of the asteroid they are also attractive throughout the interior.

In the past asteroids might have been spinning about other axes than that of maximum moment of inertia. The spin rate would then be faster and these excess rates could have peeled off the requisite outer layers to produce a stable configuration. The fact that carbonaceous chondrite material is very friable and that 1566 Icarus and 321 Florentina are surprisingly spherical for their sizes and rotation rates adds credence to this idea; however more observations of small asteroids are needed to confirm this thesis.

Flipping rings in proteins

from G. C. K. Roberts

X-RAY crystallography has given us a very detailed picture of the structure of many proteins. This picture is, however, a static one, and in recent years there has been much interest in attempts to understand in detail the dynamics of protein structure. Nuclear magnetic resonance (NMR) spectroscopy is potentially able to give information on the rate of motion of individual amino-acid sidechains within a protein. The complexity of the NMR spectra of proteins often makes this information difficult to extract, but recently several reports have appeared which focus on the motional characteristics of the aromatic rings of tyrosine and phenylalanine residues.



Sykes and his colleagues have been studying the alkaline phosphatase of *Escherichia coli*, labelled *in vivo* with 3-fluorotyrosine. The ^{19}F NMR spectrum shows a separate resonance for each of the 11 tyrosine residues per subunit, and a thorough study of the ^{19}F relaxation behaviour has allowed Hull and Sykes (*J. molec. Biol.*, **98**, 121, 1975) to draw a number of interesting conclusions about the motion of these tyrosine side chains. They observed that the linewidth of the ^{19}F resonances (related to the relaxation time T_2) was markedly frequency dependent, becoming greater at higher frequency. One relaxation mechanism which would be expected to give rise to a frequency-dependent T_2 is chemical shift anisotropy relaxation. The chemical shift of a nucleus is a tensor quantity which depends on the orientation of the molecule with respect to the external magnetic field. In liquids, the tumbling of the molecule averages the chemical shift over all orientations, but the resulting fluctuations in Zeeman energy provide a relaxation mechanism which is most effective at high fields and for nuclei (such as ^{19}F) which have a large chemical shift anisotropy. The linewidths of 9 of the 11 fluorotyrosine resonances could be explained in this way, and this analysis led to estimates of the rate of internal motion about the C_β–C(1) bond ranging from 10^6 to 10^8 s^{-1} (the overall tumbling of the protein having a rate of about 2×10^6 s^{-1}). For two of the tyrosines, there was an additional contribution to the linewidth from exchange, and for these the rate of reorientation of the ring was slower, in the range 10^2–5×10^4 s^{-1}. Analysis of the spin-lattice relaxation time and of the dipolar contribution to T_2 led to an upper limit for motion about the C_α–C_β bond of 10^6 s^{-1}.

In favourable circumstances, analysis of the ^{1}H spectrum of tyrosines and phenylalanines in proteins can give a rather direct indication of the rate of rotation about the C_β–C(1) bond. This bond lies along the symmetry axis of the aromatic ring (see figure). In the free amino acids or simple peptides, the 2 and 6 protons and the 3 and 5 protons are equivalent, and a simple spectrum is observed. For a tyrosine or a phenylalanine in a protein, such a simple spectrum will be observed only if either the environment of the two sides of the ring is identical—an unlikely coincidence—or the ring is rotating sufficiently rapidly for the 2 and 6 and 3 and 5 protons, respectively, to experience an average environment. Roughly speaking, a rotation about C_β–C(1) of approximately 200 s^{-1} will be sufficient to produce this averaging.

In hen lysozyme, all three tyrosine residues show simple spectra indicative of averaging about C_β–C(1) (Campbell, Dobson and Williams, *Proc. R. Soc. Lond.*, **B189**, 503–509; 1975). The bovine basic pancreatic trypsin inhibitor has four tyrosine residues, whose resonances have been assigned to individual residues in the sequence (Snyder *et al.*, *Biochemistry*, **14**, 3765; 1975). Three of these show simple spectra at room temperature, while the fourth, Tyr 35, shows a complex spectrum indicative of slow rotation (Snyder *et al.*, *op. cit.*, Wüthrich, presented at *Conference on Molecular Structural Methods in Biological Research*, *Stanford*, Oct. 9-10, 1975). Similar phenomena are seen for the phenylalanine residues (Wüthrich and Wagner, *FEBS Lett.*, **50**, 265; 1975). Values for the activation energies can be obtained by temperature studies (Wüthrich, *op. cit.*).

It thus seems to be rather common for the aromatic rings of tyrosine and phenylalanine residues in proteins to rotate (the motion is in all probability essentially a flip through 180°) at rates greater than 200 s^{-1}. Some of the implications of this are brought out in a recent paper by Gelin and Karplus (*Proc. natn. Acad. Sci. U.S.A.*, **72**, 2002–2006; 1975). These authors have calculated the energy barriers to rotation about C_β–C(1) of the tyrosines of the basic trypsin inhibitor, based on its crystal structure, which is known to high resolution. For both the crystallographically determined structure and an energy-refined version thereof, the barriers are extremely high (up to 230 kcalorie mol^{-1}). If the protein structure was allowed to 'relax', however, (simulated by energy minimisation with the tyrosine ring in its minimum and maximum energy orientations), a drastic reduction in the barriers could be achieved at the cost of a rather modest amount of bond angle strain. In this case, at least, it appears that a significant "breathing" of the protein is required to permit the aromatic rings to flip at the rates implied by the NMR experiments.

review article

The protein gap

J. C. Waterlow & P. R. Payne*

The concept of a worldwide protein gap, derived from the diagnosis of kwashiorkor as a protein deficiency state, is no longer tenable. Current estimates of children's protein and energy requirements are considered realistic, and by these criteria the problem is mainly one of quantity rather than quality of food.

"It is a most nourishing and stimulating diet to eat one's own words" (attributed to Sir Winston Churchill)

In 1968 the UN Advisory Committee on the Application of Science and Technology to Development presented a report to UNESCO with the title "International action to avert the impending protein crisis"[1]. Numerous recommendations were made about methods of increasing protein supplies, the production of high protein foods and the exploitation of unconventional sources of protein to fill the "protein gap". Seven years later there is a strong body of opinion that this is an incorrect statement of the problem: that what the world with its expanding population has to face is primarily a food gap or an energy gap and not a protein gap. McLaren, in his stimulating article "The great protein fiasco"[2], has summarised the history of this preoccupation with protein and in particular the reasoning by which the UN agencies came to identify protein as the weak point in the world's nutritional defences. It all began with kwashiorkor.

When Williams described kwashiorkor in young children in Ghana some 40 years ago[3], she diagnosed it as a nutritional disease, adding cautiously "... in which some amino acid or protein deficiency cannot be excluded". The children who developed the disease did so after weaning, when they were fed on starchy porridges rather low in protein, and they were cured by milk. It took some time for the diagnosis of protein deficiency to be generally accepted; in earlier accounts, particularly from Latin America, the presence of oedema and skin lesions in many cases led to the suggestion of a multiple vitamin deficiency. For the past 25 yr, however, the view has been fairly generally held that the two extremes in the spectrum of childhood malnutrition—kwashiorkor and marasmus—represent conditions in which the main limiting factor is protein on the one hand, energy on the other. This satisfying hypothesis is epitomised in the title of a book published in 1968—*Calorie Deficiencies and Protein Deficiencies*[4].

The chain of argument which leads from these early clinical studies to the concept of the protein gap as a worldwide problem rests on three premises: that kwashiorkor is indeed a manifestation of protein deficiency; that it is very common in the developing world; and that wherever kwashiorkor occurs milder forms of protein deficiency must be widespread, affecting far more children than those who develop the severe disease. This is the "tip of the iceberg" theory. All three premises need to be examined.

Is kwashiorkor a result of protein deficiency?

The evidence is to a large extent circumstantial. Retrospective dietary histories are of limited value because the illness itself causes a fall in appetite and thus a reduced intake of all nutrients. The most powerful evidence of cause and effect in nutritional work—the therapeutic test—is not practicable, because a sick child cannot be fed protein alone. Brock *et al.*[5] attempted this approach when they produced "initiation of cure" (loss of oedema) with a diet in which the only source of nitrogen was a mixture of pure amino acids, but they had to give a source of energy as well. Some of the biochemical features of kwashiorkor, notably the low serum albumin and altered amino acid pattern[6,7], indeed suggest a state of protein depletion. Nevertheless, our understanding of the pathogenesis of the major features of kwashiorkor, oedema and fatty liver, is still incomplete. It is reasonable to suppose that oedema results in part from the low serum albumin concentration, although not all workers agree. Evidence suggests that the most likely cause of fatty liver is a failure of synthesis of the protein part of the lipoprotein which is responsible for fat transport out of the liver[8,9]. Animal experiments have also provided useful evidence: the rat is a poor model, but many of the features of kwashiorkor have been produced in pigs[10] and in monkeys[11] by feeding a diet high in carbohydrate and low in protein. Grimble and Whitehead[12] found, however, that in pigs the biochemical changes typical of kwashiorkor did not appear until the appetite of the animals had fallen, so that their food intake was reduced. The evidence is therefore not clear cut, but one difference between kwashiorkor and marasmus is undeniable: children with kwashiorkor must have been less energy-deficient than those with marasmus, for the simple reason that their bodies contain more fat, as is immediately obvious at autopsy.

The first serious attack on the conventional theory came from Gopalan in India[13]. In a prospective study of children in a poor community no quantitative or qualitative differences in the diet were found between children who developed kwashiorkor and those who became marasmic. Gopalan therefore suggested that it is not the diet which determines the clinical picture, but the way in which the subject adapts or fails to adapt. One explanation[14] (which does not take us very far) for a difference between children in their response to an inadequate diet lies in the known variability between individuals in their requirements for energy and for protein. One could conceive that on a diet which is marginally deficient in both, a child who happened to have a high energy requirement would develop marasmus, and one with a high protein requirement would develop kwashiorkor.

---

* Address: Department of Human Nutrition, London School of Hygiene and Tropical Medicine, London, UK.

The basis for intra-individual variation in requirements is quite unknown. One may speculate a little further. When energy intake is inadequate, protein, mainly from muscle, is oxidised to fill the gap. It has been said that the marasmic lives on his own meat; that is, that the net efflux of amino acids from muscle provides enough substrate for synthesis by the liver of albumin and apolipoprotein, so that the characteristic features of kwashiorkor do not appear. The release of amino acids from muscle, and the extent to which they are utilised for protein synthesis in other tissues or for gluconeogenesis, probably depends on the balance of at least three and possibly four hormones—insulin, cortisol, glucagon and growth hormone. Whitehead *et al.*[15] have described progressive disturbances in endocrine balance in kwashiorkor and there is some evidence of endocrine differences between kwashiorkor and marasmus[16]. Again we do not know whether these are effects of distinct causes or whether they represent the inherent variability of response.

Finally, there are differences, which may be important, in the natural history of kwashiorkor and marasmus. It is often said that marasmus typically occurs at an earlier age, but this is not universally true. Within each of the three countries—Jamaica, Iraq and Jordan—for which we have comparable data, there seems to be no significant difference in the age at which the different types of case present at hospital. In all three series, however, the marasmics were more stunted in height than the children with kwashiorkor[17-19]. The same has been found in unpublished studies from Sudan and Nigeria. This is clear evidence that marasmus is a more long standing condition and that its onset must have been earlier. It has also been suggested that kwashiorkor is typically precipitated by an acute infection such as measles, whereas marasmus infection for example, gastroenteritis[2], tends to be chronic and recurrent.

Table 1 Estimates of protein and energy requirements at 1 yr of age

Year	per kg body weight Protein* (g)	Energy† (kcal)	 (kJ)	Protein energy / Total energy (%)	Source	Reference

Many readers may regard this discussion of the characteristics of childhood malnutrition as academic and irrelevant to the question of the protein gap, but it is important to realise how much is still unknown about the way in which children adapt or fail to adapt to deficient diets. This lack of knowledge has practical importance.

Is kwashiorkor common?

When the WHO and FAO became concerned about childhood malnutrition after the war, one of the first results was a survey in Africa by Brock and Autret[20]. Their report concluded that "kwashiorkor is the most serious and widespread nutritional disorder known to medical and nutritional science". McLaren[2] has pointed out that this judgment, based largely on rural Africa, ignores large areas of the world where marasmus is by far the commonest form of malnutrition. It is also frequently said that kwashiorkor is a rural, marasmus an urban, disease; and that marasmus is getting commoner because of increasing urbanisation and decreasing breast feeding. These statements are plausible, but they are not supported by firm epidemiological evidence. The reason is not just a lack of adequate surveys, but also the lack of an agreed and standardised system of reporting, without which it is impossible to make comparisons between different regions or to identify changes that are occurring with time. If, as the literature suggests, the prevalence of kwashiorkor differs in different countries with different dietary patterns, there should here be an important clue to aetiology[17]. This clue has not, however, been systematically followed up.

Is there evidence of widespread protein deficiency in the absence of clinical disease?

Estimates by WHO[21,22] that in many countries 20–40% of children are moderately or severely malnourished are in most cases based on a deficit in weight for age. This growth failure is, of course, a nonspecific effect of malnutrition. It is possible that more information may be obtained by analysing separately two components of growth failure: inadequate gain in weight and inadequate gain in length or height[17,23].

The search for specific biochemical indicators of protein deficiency has been going on for many years. Whitehead, a pioneer in this field, has concluded that the most sensitive index of impending kwashiorkor is a decrease in serum albumin concentration[24]. The greater precision of modern automated methods makes it possible to detect small deviations from accepted normal levels that are statistically significant. It remains to be proved, however, that this change is indeed a specific effect of protein deficiency.

The third approach is by comparison of intakes with requirements. Before going on to this we have to consider the basis on which requirements have been estimated, since they are often considered not to be realistic, or little better than guesses.

Estimates of requirements

Table 1 shows how estimates of the requirements of a 1-yr-old child for protein and energy have changed over the years.

Protein requirements. The figure of 1.27 g kg^{-1} in terms of milk protein is in our view very well founded. It is easier to estimate the requirement of an infant than of an adult because growth provides an extremely sensitive criterion of whether the child's needs are being met. In infants up to about 6 months the requirement is based on the observed intakes of infants consuming breast milk freely and growing normally[25]. This could even be slightly more than the minimum requirement. At about 1 yr the requirement has been derived from measurements of the minimum amount of cow's milk protein necessary to secure normal growth[26]. As might be expected, it is slightly less per kg than that of the younger infant who is growing faster. Of the requirement of 1.27 g kg^{-1}, it is calculated that about seven-eighths is needed for maintenance and only about one-eighth for growth[25]. We have found that if the protein intake of infants is reduced from an adequate to a maintenance level, with no change in energy, growth falls off within 1 or 2 d. It seems that the amount used for maintenance is so closely fixed that there is no margin to supply the needs for growth if the intake is slightly reduced.

In an adult man the latest estimate of protein requirement[27], in terms of egg protein, is 0.57 g kg^{-1} d^{-1}: about half that of the 1-yr-old child. This figure is derived from the amounts of protein needed to secure nitrogen balance. For an adult of average weight this comes to about 40 g of milk or egg protein per d, or about 60 g if corrected for the lower protein quality of the average mixed diet. This is about two-thirds of the amount of protein eaten daily by most people in this country. Many people feel strongly that these estimates of protein requirement are unrealistically low, and that the protein gap has been artificially abolished by the stroke of a pen, simply by reducing the requirement. If the estimates for infants are well founded, however, it is difficult to see why those for adults should not be correct. The lower requirement for the adult is not due simply to the absence of growth; the adult is considered to have a lower maintenance requirement, and this makes sense, because the rate of many metabolic reactions decreases with increase in body weight. Examples are the basal oxygen uptake, the rate of total protein turnover[28] and the rate of albumin synthesis[29,30]. Young *et al.* have shown a close correspondence between protein requirements and protein turnover rate over a whole life span, from prematurity to old age[31].

Table 2 Protein quality of cereals determined in different ways

	Utilisable protein as % of total energy Method of determination			
	NPU (rat)	NPU (child)	Protein score	Average
Maize	4.7	4.8	5.4	5.0
Millet	5.3	5.3	7.7	6.1
Rice	4.9	6.1	6.5	5.8
Wheat	5.9	5.2	5.6	5.6

Protein quality. The protein requirement of 1.27 g kg^{-1} d^{-1} is in terms of milk protein, which is almost 100% utilised when fed at or below the requirement level[26]. In fact, at the age when children develop kwashiorkor they are not fed on milk alone, and so this figure has to be corrected for the quality of the dietary protein. There is much difference of opinion about methods of determining protein quality[32], and, in particular, whether biological values determined on rats are applicable to man. In theory, results on the rat should underestimate quality, because the rat is growing faster than the child. Protein quality depends on the proportion and pattern of the essential amino acids. The essential amino acid requirement for maintenance is relatively low, because recycling of these amino acids is extremely efficient[33,34]. For growth, however, the essential amino acids have to be provided by the diet for deposition in tissue protein. The proportion of essential to total amino acids in the diet must therefore in theory be higher the faster the growth rate. Nevertheless, as Table 2 shows, values for the protein quality (utilisable protein content) of cereals measured directly in rats and in children are in good agreement, and agree also with theoretical estimates based on the proportions of essential amino acids in these proteins (protein scores).

For many purposes it is convenient to convert the amount of utilisable protein provided by a diet or foodstuff from units of weight to units of energy, and to express it as a percentage of the total energy. This is the *P/E* ratio. The figures in Table 2 are expressed in this way. For comparison, the *P/E* ratio in breast milk (early lactation) is about 7.5%, falling to 5% at 2.5 to 3 months of age[35].

Energy requirements. Estimates of the energy requirements of young children have changed less than those for protein (Table 1). The energy requirement is made up of three components—maintenance, growth and physical activity, and we now have fairly reliable figures for each of these. It has been found in a number of animal species, including man, that the maintenance requirement—that is the minimum energy intake at which body weight is constant—is about 1.5 times the basal metabolic rate (BMR)[36]. In the 1-yr-old child the BMR is 210–230 kJ kg^{-1}, so that the maintenance requirement may be taken as 330 kJ kg^{-1}. Studies in children recovering from malnutrition and gaining weight very rapidly have shown that the energy cost of weight gain is about 40 kJ kg^{-1} (ref. 37), if it is assumed that the tissue deposited contains normal amounts of protein and fat. This figure includes both the stored energy and the energy cost of synthesis.

More recent work in Jamaica by Spady (unpublished) suggests that this is an overestimate. He obtained a figure of about 20 kJ per g weight gain. This is the lowest yet found, but is still higher than the theoretical cost of peptide bond and fat synthesis. The rate of weight gain in a normal infant at 9–12 months would be about 1 g kg^{-1} d^{-1}. If we accept the conventional estimate of 430 kJ kg^{-1} for the total daily requirement, this would leave 80 kJ d^{-1} for physical activity. Until very recently these components of energy expenditure in infants have not been studied directly. Spady obtained experimental confirmation of the maintenance energy needs of young children with the instrument known as the SAMI, which counts and integrates the total number of heart beats. After calibration in each child it is possible to monitor the total energy expenditure over a whole day without interfering with the child's activities. Very good agreement was found between energy intake from food and the sum of energy expenditure and energy stored during growth. These results suggest that the estimate of the amount expended in physical activity is reasonable, although of course there will be much individual variation.

Table 3 Energy and protein intakes of children aged 1–2 yr in various countries. Individual weighed intakes after weaning

		Average intake per kg body weight	
Country	No. of child days	Protein (g)*	Energy (kJ)
Ghana	30	1.19	360
Guatemala	28	1.16	323
Jamaica	266	1.47	348
Polynesia	72	1.32	295
Thailand	54	0.61	218
Uganda	124	1.28	285

Sources given in ref. 17.

*As protein which is 100% utilised. Utilisation of protein in actual diets assumed to be 60%.

Perhaps the most important conclusion from this "dissection" of energy expenditure is that the maintenance requirement is relatively so large. An intake of about 320 kJ kg^{-1}, which is quite common in children in developing countries (Table 3) is just enough for maintenance, with no margin for growth or extra activity. Quite apart from the physical effects, this limit on intake may also be bad for the child's mental development, as it will reduce exploration, play and social activity.

Individual variation. The estimates which have been given of protein needs represent what have been called 'safe levels'[27]. These are amounts sufficient to meet the needs even of individuals having unusually high requirements, and are obtained by adding

2 standard deviations (+30%) to the average requirement. In fact, this estimate of 15% for the variability between individuals is almost certainly too high[38], so that the safe levels are very safe

For energy, on the other hand, there is the complication that the cause of variation is partly metabolic and physiological, because of differences in maintenance expenditure and growth rate, and partly due to differences in physical activity. The only estimate we can make of the first source of variation is from measurements of basal metabolic rate, of which the s.d. may be taken as 6.5% (ref. 39). That of the second component—physical activity—will presumably be much larger. With energy, to add a margin of safety will mean that those who need less get too much, and the figures quoted in Table 1 are therefore simply the average values for groups of children.

Comparison of intakes and needs

The question originally posed was whether there was evidence of widespread protein deficiency in children. It would be more precise to ask whether there is evidence that protein is limiting. If the total food intake is inadequate there will be a secondary protein deficiency, because protein cannot be utilised if energy is lacking, and extra protein will be of no value. To answer the question, accurate measurements have to be made of the actual food intakes of individual children, and not simply of the family as a whole. Moreover, because of the difficulty of measuring intakes of breast milk, they must be made on children who have been completely weaned. Studies which fulfil these criteria have been made in a number of countries, but even so, when the literature was summarised two years ago[17], the number of child days covered by the measurements was very small in relation to the importance of the problem. With one exception, all these studies showed that in children 1–2 yr old there was a greater deficit in energy than of protein (Table 3).

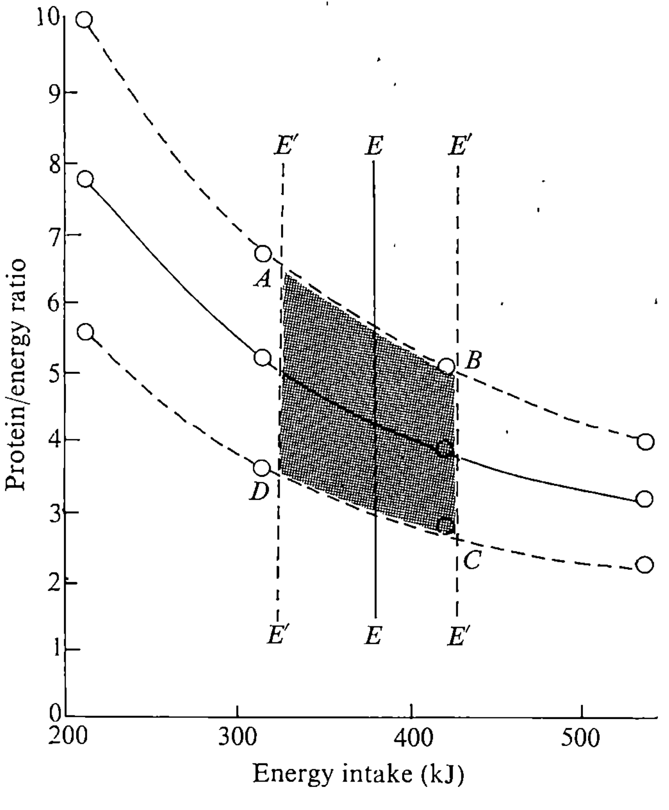

Fig. 1 Ratio of utilisable protein (kJ) to total energy of diets which will provide the average requirement of protein (———) and the average ±2σ (dotted curves), for a 1-yr-old child The top curve represents the "safe level". Vertical lines are estimates of the energy requirement for maintenance + growth + minimal physical activity. The solid line is the average, the dotted lines the average ±2σ The shaded area is the "area of ignorance" resulting from the ranges of individual variation.

Another study in Uganda[40] showed energy intakes 30% below the recommended level, with a marked reduction in physical activity compared with European children. These results are of particular interest because they were obtained in a district where kwashiorkor has long been considered the typical form of malnutrition.

It is obvious that to prevent malnutrition the energy deficit shown in Table 3 must be made up. It then becomes important to define the kind of diets which will fulfil protein needs when enough is eaten to satisfy energy needs. The figures already given show that at 1 yr the protein requirement, expressed as a proportion of the energy requirement, is 5%, so that in theory a diet with a P/E ratio of 5% should meet the child's needs if enough of it is eaten. The problem, however, is complicated by the individual variability of requirements[41].

Figure 1 shows the P/E ratios in diets which will provide the safe level of protein when eaten at different levels of energy intake. The vertical line E–E is an estimate of the minimum energy requirement for health, and represents the requirement for maintenance and growth, with a very small addition for physical activity. This estimate is an average: we do not know the extent of individual variation, so the best we can do is to assume it to be the same as for the BMR, that is about 6.5% (ref. 39). The lines E'–E' represent $E\pm2\sigma(\pm13\%)$. The point A represents the "worst" case, of a child who has the highest need for protein and the lowest for energy. The corresponding P/E ratio is 6.5%. Conversely, the child at C has the lowest protein and highest energy need. A and C then represent the extremes of the range of P/E ratios needed if protein and energy requirements are negatively correlated—a very unlikely situation. Similarly, points B and D represent the range of P/E ratios in a population in which the two requirements are positively correlated. B corresponds to a P/E ratio of 5.0%. There could, of course, be intermediate situations with protein and energy needs being more or less independent in a random fashion (zero correlation). Beaton and Swiss[42] suggested a value of +0.2 for the correlation coefficient. This may be too low, if, as in this case, we are discussing a situation in which physical activity, and thus its contribution to the variance, is low. Protein turnover is a process which is expensive in energy and therefore accounts for a substantial part of the basal energy requirement. The demonstration by Young *et al.*[31] of a parallel between protein turnover rate and requirement has already been mentioned. These considerations suggest that there is likely to be a fairly strong positive correlation (> +0.2) between individual needs for protein and energy.

All we can say so far is that the safe level for the P/E ratio is unlikely to be greater than 6.5% or less than 5.0%, and more research is needed to fill this gap. This is not academic hair-splitting but of great practical importance. Reference to Table 2 shows that the P/E ratios of cereals fall within the likely range of the safe level. The suggestion that cereals without any supplement might provide safe amounts of protein for weaning children may be unacceptable to many. Begum *et al.*[43] have shown that normal growth could be sustained in 2–3-yr-old children by diets in which wheat or rice were the sole sources of protein, but up to now this has not been demonstrated for younger ages. A more precise knowledge of the safe P/E ratio would enable us to assess the significance of the relatively small differences between the cereals; for example, is the somewhat lower value for maize related to the clinical impression that kwashiorkor is commoner in areas where maize is the staple food? The main disadvantage of cereals, and particularly maize, as a principal food for young children is, however, that their bulkiness when cooked makes it difficult for the child to eat enough to satisfy his energy needs, unless—as is unlikely—he has very frequent meals.

The effect of infections

The estimates of protein and energy requirements proposed by FAO/WHO[27] are for healthy people. Even before their latest report was published, its recommendations on protein requirements were described by the Protein Advisory Group of the UN as inadequate, on the ground that no allowance was made for the effect of infections. The argument was that since infections cause a loss of body nitrogen, a high protein supplement is needed to make good these losses. We do not know what is the extent of the nitrogen loss in conditions of real life (as opposed to a metabolic ward). The loss of nitrogen must, however, be accompanied by a loss of energy stores because of the reduced food intake and the extra heat production caused by fever. The extent of these losses is again unknown, but perhaps the problem can be tackled in a different way. The child with an infection ceases to gain weight and very often loses weight. We may then ask, what is the diet necessary for him to catch up and regain his correct weight after the infection is over? If the child has been at constant weight for a month, he needs to gain at twice the normal rate for the next month in order to catch up. Table 4 shows the average *P*/*E* ratio needed for different rates of catch-up. Whitehead[44] has published a similar table, using a different value for the energy cost of growth. Even at rather high growth rates, the required increase in protein content is not very great. Whitehead and his colleagues in Gambia (personal communication) have studied the interrelationship of three factors in rural children: food intake, weight gain and the number of days per month that the children were ill. A higher food intake, derived from the usual diet only, with no supplements, had a very clear effect in counteracting the growth failure caused by infections.

Table 4 Protein and energy requirements for catch-up growth

	Protein ($g\ kg^{-1}\ d^{-1}$)	Energy ($kJ\ kg^{-1}\ d^{-1}$)	*P*/*E*
Maintenance	1.10	440	4.2
Maintenance + normal growth × 1	1.25	465	4.55
Maintenance + normal growth × 2	1.40	490	4.8
Maintenance + normal growth × 3	1.55	515	5.05
Maintenance + normal growth × 4	1.70	540	5.3
Maintenance + normal growth × 5	1.85	565	5.5

Protein increment for normal growth taken as 0.15 $g\ kg^{-1}\ d^{-1}$. Maintenance requirement for energy includes normal level of physical activity. Maintenance requirement for growth taken as 25 kJ per g weight gain.

Another stress is pregnancy. In communities where the women are undernourished a high proportion of infants are born with a low birth weight. Work in Guatemala[45] has shown that increasing the mother's energy intake during the last trimester of pregnancy by a total of 9 MJ or more (as carbohydrate) caused a significant increase in birth weight and a reduction in the infant death rate in the first year of life.

Understanding and prevention

The evidence we have put forward leads to the conclusion that the protein gap is a myth and that what really exists, even for vulnerable groups, is a food gap and an energy gap. This point of view is now fairly widely accepted, particularly in this country, where it has become part of aid policy[46]. What needs to be done to fill the gap is another story. It is important that scientists in this field should make sure that the pendulum does not swing too far. One difficulty is that the controversy about the protein gap, which represents a genuine difference of scientific opinion, is accompanied by another controversy, potentially far more dangerous. This arises from the attitude that research on these nutritional problems is academic, irrelevant and a waste of time; that we know how to prevent malnutrition and therefore what matters is to use this knowledge. Malnutrition is an emotive subject; it is certainly true that there is much that can be done with existing knowledge, and that action cannot wait on the perfectionism of research. But perhaps the story of the protein gap shows the arrogance of supposing that we know the answers, and illustrates the need for a continuing critical examination of the premises on which action is based.

In the long run, the prevention of malnutrition must be founded on an understanding of how the body adapts to different dietary situations, because otherwise concepts such as "deficiency" and "requirement" have no meaning. This is particularly important in relation to marginal states of malnutrition. Nutrition has been called the "Cinderella of the sciences"—justly so, because like Cinderella it is pulled in two directions.

Lunar temperature and global heat flux from laboratory electrical conductivity and lunar magnetometer data

C. P. Sonett

A. Duba

University of California, Lawrence Livermore Laboratory, Livermore, California 94550

Three-layer monotonic electrical conductivity models for the lunar interior to a depth of 600 km are used in conjunction with laboratory measurements of the electrical conductivity of olivine and pyroxene to estimate a temperature–depth profile. The temperatures calculated for depths of 400–600 km are consistent with attenuation of the seismic shear wave. The temperature calculated at a depth of 100–250 km yields a heat flow that is in good agreement with the directly measured lunar heat flow. The temperature, however, is sufficiently close to melting that mascon anisostasy would not be maintained. Thus a better conductor is required at this depth.

THE internal temperature of the moon has been calculated using a set of monotonic conductivity three-layer models derived from Lunar Surface Magnetometer (LSM) data[1] together with laboratory determined conductivity–temperature relationships for two minerals, orthopyroxene (OPX)[2] and olivine (OL)[3], thought to be representative of the interior of the Moon.

The three-layer model is characterised by a core, shell, and crust. The latter has a vanishingly small electrical conductivity. Although the shell and core conductivities can be specified over a broad range of depths, only the conductivities at R_1 (the radius of the core) and R_2 (the outer radius of the shell) are really relevant. This is due to a very strong bias in favour of the outer edge of a layer, because this is where the relevant frequencies tend to be most damped[4]. Resolution tests (Schubert, personal communication) confirm this. Thus the shell conductivity refers to a depth of ~ 150–250 km, depending on circumstances to be discussed here, whereas the core conductivity refers to a depth of ~ 450–600 km. Deeper conductivity cannot be calculated with any confidence from the data in this paper.

For the monotonic three-layer conductivity model, variations in R_1 and R_2 occur because of uncertainty in the estimate of lunar higher order magnetic excitation. The addition to the nominal dipole excitation is primarily from the induced quadrupole moment. The multipolarity arises from higher orders of the field associated with finite wavelengths in the solar wind. For quadrupole and higher order, the direction of the convected wave fronts in the solar wind must be found to determine the pseudoscattering angle, θ. (The term pseudoscattering angle is used to signify that, although the theory of lunar induction is formally similar to Mie scattering, in the case of perfect confinement of the induced field, no field can be radiated. In the restricted theory of lunar induction, however, displacement currents are ignored, and thus only a near field is present.)

This angle, which affects estimates of the higher order induction, is defined as the angle between the phase front vector of the incoming radiation and the lunar radius vector to the site of the LSM. An additional variation in the magnitude of higher order induction arises from uncertainty in the wave phase velocity, U_p. This is generally less than the convected speed of the solar wind. (See refs 5, 6 for the scattering geometry.)

Here we restrict the pseudoscattering angle to $\theta = 150°$, a reasonable approximation for a combination of Alfvén waves propagating down the spiral field direction and tangential discontinuities being convected in the solar wind. Changing either U_p or θ affects R_1, R_2 and the respective conductivities similarly; therefore, we have chosen to vary U_p and maintain θ constant. In general, changes in θ do not produce major changes in the conclusions, except perhaps in the calculation of the heat flux.

Inversion of lunar transfer functions to yield a suite of monotonic three-layer models is based on spherically symmetric plasma confinement theory (SSP)[7]. This leads to an underestimate of electrical conductivity, because, on the Moon, field lines are carried from the front side to the diamagnetic cavity on the antisolar hemisphere, depressing the sunward response[8,9]. This effect is expected to result in a slight upward revision of the temperature estimate when the full asymmetric theory, incorporating the angular spectrum of the wave field, is available.

The dependence of electrical conductivity on temperature was determined in the laboratory using mixed gases to maintain oxygen fugacity at a value within the stability field of the mineral to be measured. The electrical conductivity of the olivine used here is that reported by Duba *et al.*[3] from the Red Sea. Conductivity has been determined with a gas mixture which produces an oxygen fugacity of 10^{-3} Pa (10^{-8} bar) at 1,200 °C. More experimental details and information on gas mixtures may be found in Duba and Nicholls[10]. The OPX conductivity was determined up to 1,400 °C on a sample of the Bamle enstatite[2] previously used for shock compression measurements[11]. OPX_1 refers to measurements for $10^{-3} \leqslant f_{O_2} \leqslant 10$ Pa at 1,200 °C and hydrostatic pressure of 0.5 GPa; OPX_2 refers to measurements for $f_{O_2} = 10^{-3}$ Pa at

1,200 °C and hydrostatic pressure of 0.1 MPa. The electrical conductivity of the enstatite fits the formula

$$\sigma = \sigma_0 \exp(-\varepsilon/kT).$$

A change in the conduction mechanism at ~1,300 °C in the Bamle OPX is suggested by a change in σ_0 from ~ 10 to 30 MS m^{-1} and the activation energy, ε, from 1 to 3.2 eV.

Deep conductivity

Figure 1 shows the temperature at a depth between 450 and 600 km using OPX_1 (lower trapezoid), and OPX_2 and OL (upper trapezoid). In the latter case the temperatures derived from the two minerals are indistinguishable. Both the vertical and horizontal spreads are associated with the influence of higher order modes in the lunar excitation, which affects the calculation of temperature. The variations are due to changes in the assumed value of U_p where $200 \leqslant U_p \leqslant 400$ km s^{-1}, changing the radii within the range $1,200 \leqslant R_2 \leqslant 1,280$ km and the electrical conductivity between $1.6\times10^{-3} \leqslant \sigma \leqslant 1.8\times10^{-3}$ S m^{-1}. The lower trapezoid shows a temperature range of only about 30 °C. All temperatures for R_1 are within ~ 100 °C, or less, of the Ringwood–Essene solidus[12]. This close approach to the solidus is entirely consistent with the attenuation of seismic shear wave depths variously estimated to lie between 500 and 800 km (ref. 13). From calculations of Schubert *et al.*[14] using a lunar model with an isothermal Fe core, convecting shell, and conducting lithosphere, the temperature at the depth discussed here is also consistent with those shown in Fig. 1 based on electrical conductivity.

Corrections to the data for diamagnetism and asymmetric induction would have opposite effects, the former to lower the estimated temperature and the latter to raise it. Diamagnetism requires a pressure gradient which balances the Lorentz force[15]. The slowing of the bulk flow of the solar wind ions at the Apollo 12 site has been attributed to interaction with the remanent field[16]. The slowing of the flow corresponds to the loss of ~ 19% of the free stream flow energy. This effect is the only report from lunar data from which evidence of a pressure gradient might be inferred. The effect of asymmetric induction is of the same order at high frequencies[17].

Although a final assessment of the two effects cannot be made at present, the close correlation of Apollo 12 and 15 data suggests, in any event, that diamagnetism is not important. It could have a role only at Apollo 12, since the interaction with the solar wind is weak or nonexistent at Apollo 15.

For completeness, we have also included data in Fig. 1 from Dyal *et al*[18]. The temperature extremes are calculated from their conductivity estimates using OPX_1. Their 'mean' is shown as the dashed line approximately bisecting their extremes, shown by the shaded region. The temperature profile from the present work is generally consistent with their 'mean', although their estimate of the near-surface temperature is sufficiently low to perhaps satisfy a single mineral composition Moon without involving the problem of mascon anisostasy discussed in the next section. Their deep temperature is depressed somewhat from our estimate, but sufficiently near the solidus to still infer the possibility of shear wave attenuation. The most recent analysis of transients by Dyal *et al.*[19] shows a temperature profile, however, which exceeds the Ringwood–Essene solidus in the outer 500 km of the Moon.

Shell temperature and mascon anisostasy

The three-layer model gives two internal temperature estimates for a specified U_p. Varying U_p between the limits $200 \leqslant U_p \leqslant 400$ km s^{-1} and fixing θ = 150 ° as before, the outer edge of the shell is $1,520 \leqslant R_2 \leqslant 1,600$ km. The corresponding electrical conductivity is $2.9 \times 10^{-4} \leqslant \sigma \leqslant 5.5\times10^{-4}$ S m^{-1} and the temperature is $1,110 \leqslant T_2 \leqslant 1,210$ °C. These values define the two trapezoids to the left side of Fig. 1. The conductivity at depth R_2 is determined strongly by the higher frequencies in the solar wind. Thus higher order modes are here more important than for the conductivity at R_1. For example, for θ = 180° and U_p = 200 km s^{-1}, R_2 = 1,660 km—a depth below the surface of only 80 km. We believe that real resolution at this depth is not attainable without higher frequency data. It is interesting to note that as the position of R_2 moves out with change in induction geometry, the electrical conductivity estimate is depressed, thereby tending to hold the thermal gradient fixed.

From Fig. 1 it is evident that the temperature calculated from OPX_1 is within 100 °C of the solidus of the model lunar pyroxenite of ref. 12. This proximity places a severe constraint on the rigidity of the lithosphere required to maintain the anisostasy of the circular mare mascons[20]. Although the thickness of the lithosphere is uncertain and depends on the viscosity and thermal gradient, a thickness of at least 200–300 km is commonly assumed. We note that, even if the temperature estimate were reduced by estimations based on a less extreme portion of the trapezoids which encompass all the temperature estimates, little would be gained with regard to the rigidity problem. The barred portions of the trapezoids are used to denote that the temperature estimates are potentially in error because of the mascon problem, and may require downward revision. As we shall emphasise later, this implies a compositional change at this depth, but in turn raises difficulties with the heat flux from the Moon.

Global heat flux

A preliminary estimate of global heat flux can be obtained from the previous calculation of temperature at depths of 150–200 km. We have found that this is consistent with the direct heat

Fig. 1 Lunar temperature estimates from conductivity models *a*, orthopyroxene (OPX_1; ref. 2); $\sigma_0 = 3 \times 10^7$ S m^{-1}, ε = 3.32 eV for T > 1,327 °C; σ_0 = 2.03 S m^{-1}, ε = 1.05 eV for T < 1,327 °C. *b*, orthopyroxene (OPX_2; ref. 3); for T > 1,327 °C the same as in *a*, σ_0 = 3.49 S m^{-1}, ε = 1.14 eV for T < 1,327 °C; olivine[3]; σ_0 = 17.4 S m^{-1}, ε = 1.34 eV for T < 1,320 °C. *c*, Solidus (ref. 12). Solid areas, obtained from three-layer monotonic model of Sonett *et al.*[1]; shaded area, obtained from nightside and geomagnetic tail-lobe limits, based on OPX_1 (ref. 18): obtained from ———, tail-lobe mean, based on OPX_1 (ref. 18).

Table 1 Thermal gradients calculated for varying U_p and $\theta = 150$ °C in the three-layer monotonic conductivity model

U_p (km s^{-1})	R_2 (km)	T_{OPX_1} (°C)	T_{OPX_2} (°C)	T_{OL} (°C)	dT/dR ($10^5 \times$ °C km^{-1})		
					OPX$_1$	OPX$_2$	OL
400	1,519	1,210	1,240	1,230	5.6	5.7	5.7
300	1,537	1,190	1,220	1,210	6.0	6.0	6.1
200	1,600	1,140	1,140	1,140	8.2	8.4	8.4

flux measurements of Langseth *et al.*[21] but is possibly too high, for reasons given in the previous section. Table 1 shows thermal gradients calculated assuming a linear increase of temperature with depth between the surface and R_2. The thermal gradients are insensitive to variations in the relative amounts of OPX and OL. Thermal gradients (dT/dR) from Table 1 are used to construct Table 2, which shows estimates of heat flux, incorporating the variable U_p. To calculate heat fluxes in Table 2 we use an average thermal conductivity of 4.18×10^{-2} W cm^{-2} °C^{-1}, a reasonable mean between a Hortonville dunite (3.64×10^{-2} W cm^{-2} °C^{-1}) and a Bushveldt pyroxene (4.93×10^{-2} W cm^{-2} °C^{-1})[22]. Langseth *et al.*[21] report a range of heat fluxes from 2.99–3.59 μW cm^{-2} at the Hadley–Appenine site, with their best value being 3.31 μW cm^{-2}. Assuming that the most likely value for phase velocity is $200 \leqslant U_p \leqslant 300$ km s^{-1}, as seems to be the most reasonable from arguments based on the solar wind data and studies of the lunar response, the magnetometer derived heat flux is 2.5–3.5 μW cm^{-2}. This is a global or large area average and is not dependent on local variations, but is model dependent, varying with U_p and compositional assumptions.

Discussion

Subsidence of mascons may have taken place over a long period of time, but this is uncertain; they are now below the mean surface of the Moon. There is some evidence that at least some shallow zone moonquakes are connected with ongoing subsidence. Lunar transient events are thought to correlate with the ringed maria and with shallow zone quakes[23]. The Apollo 15 magnetometer anisotropy may require a dynamic process, suggesting a model of circumferential cracking at great depth. In spite of these indications of settling, the mascons seem to be anisostatic, and thus some crustal rigidity is required.

Actually the issue of mascons and isostasy seems unsettled because of the combination of lateral positive and negative anomalies across Serenitatis, for example. Hulme[24] produced a model with mass excess overlying mass deficiency to account for the negative gravity anomaly at the edges, but his model is only qualitatively correct and transforms the global problem into a problem of the stability of a more local region. He finds a negative anomaly only one-fourth of that which he quotes for Muller and Sjogren[25], and he states that it is difficult to provide quantitative consistency without changing his (Hulme's) model appreciably. Other models for the negative anomaly at the mare edge suggest a mass excess surrounded by a mass-deficient ring, correspondingly to crater excavation followed by filling[26,27]. Current mascon models are non-unique, but in the light of this paper, the seismic data, and heat flow data, we think it more likely that the mascons exhibit large scale anisostasy. A ring of mass-deficient material is consistent with this, though it should be pointed out that Hulme's model cannot yet be conclusively ruled out.

If a rigid lithosphere is required on the Moon, then the temperatures estimated from the LSM and the electrical conductivity data on OPX and OL seem to be high, and the presence of a material having a higher electrical conductivity at a given temperature is required in the outer 200±50 km of the Moon. We think that the problem of the source of the mare basalt is, as yet, too poorly understood to be able to infer a composition. The situation with the electrical conductivity–temperature functions for basalts is equally poorly understood.

Nevertheless it is worth noting that the electrical conductivity of terrestrial basalts, summarised by Duba and Lilley[28], indicates that a lower temperature at a depth of ~ 250 km may result if the outer shell of the Moon were composed of basalt. The inferred depression of the temperature would strongly affect the estimates of dT/dR and the heat flux (H) shown in Tables 1 and 2. It should be noted that all electrical conductivity measurements of basalts have been made under conditions potentially favourable to oxidation of Fe^{2+} to Fe^{3+}. Since Duba and Nicholls[10] have shown that the conductivity of olivine with Fe^{3+} may be increased by as much as three orders of magnitude, investigations of the electrical conductivity of basalt in conditions of controlled oxygen fugacity are now under way.

Table 2 Global heat flux μW cm^{-2} estimated from Table 1

U_p(km s^{-1})	H_{OPX_1}	H_{OPX_2}	H_{OL}
400	2.35	2.40	2.38
300	2.51	2.57	2.56
200	3.41	3.51	3.52

Because of the difficulties with compositional models and electrical conductivity functions, we can only say that a substantial depression of the temperature at R_2 is required to satisfy the mascon-viscosity requirement. A guess is that the outer shell temperature at R_2 is between 600 and 1,200 °C, with prejudice towards the lower value. This would immediately depress the estimated global heat flux by about a factor of two. Since Langseth *et al.*[21] inferred a global radionuclide concentration of about twice the chondritic value, the arguments given here would make the two approximately equal. These comments are based on the assumption that the Moon is at present in thermal equilibrium, a condition achievable in the present epoch only if strong convection has taken place.

Nakamura *et al.*[13] infer a thermal gradient of $2 \leqslant dT/dR \leqslant 5$ °C km^{-1} at a depth of 60 km (the bottom of their zone 1). This is a small thermal gradient, but their upper limit is consistent with a lowered global heat flux. It should be noted that the determination of the thermal gradient for the several experiments discussed here is for widely differing depths. We have assumed here that dT/dR is constant from the surface to R_2, whereas the thermal gradient probably diminishes with depth. Thus Table 2 provides upper bounds for dT/dR. The heat-flow experiment measures the heat flux in the regolith, and therefore requires a secondary experiment to determine the thermal conductivity of the regolith, which cannot be compared directly with that at 150–250 km. It is likely that the radionuclide concentration is non-uniform and that the region near R_2 contains a significant fraction of the lunar radionuclide concentration. The outward migration of the radionuclide concentration inferred by these comments means that dT/dR would be increased in the layer very near to the surface, but possibly decreased near R_2. Thus the question of the correct thermal gradient, and to which depth it refers is incompletely explored.

Conclusions

If the Moon is assumed to have a composition of OPX, OL, or a mixture of the two at a depth of 450–600 km, the temperature calculated from magnetometer data is near to the solidus of Ringwood and Essene[12]. This high temperature is in accord with the evidence from seismic data of the attenuation of shear waves at a depth of 500–800 km. A temperature from nearer to the surface, at a depth of 150–250 km, is found by assuming that the composition at shallow depth is similar to that assumed for 450–600 km. There the temperature is even closer to the melting curve. The thermal gradient inferred from the shallow temperature is consistent with the values found by Langseth *et al.*[21], but cannot provide the lithospheric rigidity needed for support of the mascons. A reduction in the estimate of lithospheric temperature can be made only if a more conducting material is present at the depths of about 150–250 km. At the same time this reduction in the lithospheric temperature depresses the calculated heat flux. Depending on the material composition, the temperature estimate using the results of Langseth *et al.*[21] could be reduced by a factor of nearly two. If heat-producing radionuclides were concentrated in the outer 60 km, the thermal gradient derived in this paper would be more in accord with that estimated by Nakamura *et al.*[13]. The reconciliation of dT/dR at 60 km inferred from the seismic data and that inferred from the conductivity data, requires further study to find the curvature in the thermal profile, that is d^2T/dR^2.

Substances which are consistent with geophysical constraints for the lithosphere, derived from the magnetometer data, include possibly basalts, but this may be inconsistent with geochemical evidence. Recent electrical conductivity measurements on the albite end member of the plagioclase series indicate that plagioclase in the lunar upper mantle would yield lower temperatures than olivine and pyroxene[29]. Petrologic models which envision an ilmenite-rich layer[30] in this region would conceivably also allow higher electrical conductivity at lower temperatures. The available magnetometer data cannot provide details of the conductivity profile; but the requirement that the conductivity–temperature dependence be greater, that is, higher conductivity for the same temperature, could easily mean a non-monotonic conductivity profile. It is unlikely, noting the requirement for a change of composition to more conducting material, that the conductivity–depth relation is monotonic. Thus the alternate model of the interior conductivity, with a narrow region of high conductivity, remains electrically valid[31] and is a plausible petrological and geophysical model.

Finally we note that in the region between R_1 and R_2, the thermal gradient, $dT/dR \sim 1\ ^\circ\mathrm{C\ km^{-1}}$, whereas the adiabatic lapse rate at these depths is $\sim 10^{-2}\ ^\circ\mathrm{C\ km^{-1}}$. It is unsafe to speculate on the possibility of solid state convection at this depth because of the paucity of data, but the evidence is not favourable. Convection at greater depths is still a possibility. It should be noted that uncertainty about the lithospheric composition would even apply if there were a little water present. Although there seem to be compelling geochemical arguments against this, it would be unsafe to draw an absolute conclusion regarding H_2O. The effect of water on the electrical conductivity has not been fully investigated.

We thank our colleagues H. C. Heard, A. J. Piwinskii and R. N. Schock for discussions and permission to use their data, and M. J. Drake, S. K. Runcorn, D. C. Tozer and G. Schubert for critical discussions. A. D. thanks ERDA and NASA, and C. P. S. thanks NASA, for financial support.

Cytological detection of mutagen–carcinogen exposure by sister chromatid exchange

P. Perry & H. J. Evans

MRC Clinical and Population Cytogenetics Unit, Western General Hospital, Edinburgh EH4 2XU, UK

A staining technique that detects sister chromatid exchanges (SCEs) has been used to examine the response of chromosomes in cultured Chinese hamster cells to a wide variety of mutagens–carcinogens. The test gives a very sensitive and rapid method for detecting chromosome mutagenicity of chemical agents and provides a powerful new method for detecting environmental mutagens.

SISTER chromatid exchange (SCE) involves a symmetrical exchange at one locus between sister chromatids, which does not result in an alteration of overall chromosome morphology. Such exchanges were originally demonstrated by Taylor[1] in autoradiographic studies of plant chromosomes and were seen as switches in radioactive label between chromatids at the second (M_2) mitosis after ^{3}H-thymidine labelling at the S phase of the M_1 cycle. Later studies showed that many of the SCEs observed in autoradiographic experiments were induced by the endogenous radiation from the incorporated tritium[2]; that the frequency of SCE was increased in cells exposed to X rays[3], ultraviolet light[4,5] and certain chemical mutagens[6]; and that a significant proportion of gross chromatid aberrations (including deletions) seemed to involve an SCE event at the site of aberration[7].

Techniques have been developed which distinguish between sister chromatids without using radioisotopes and autoradiography. These involve exposing cells to 5-bromodeoxyuridine (BUdr) for two rounds of replication so that M_2 chromosomes possess one chromatid unifilarly substituted with BUdr and its sister bifilarly substituted. Such chromatids stain differentially with Giemsa[8], the fluorochrome Hoechst 33258[9] (and various other fluorescent dyes, for example, acridine orange and quinacrine), or a combination of fluorochrome plus Giemsa—the FPG technique of Perry and Wolff[10]. At least a proportion of SCEs observed in BUdr-treated cells are induced by the analogue[11], but Latt[12] has demonstrated a fourfold increase in SCE in BUdr-treated human lymphocytes exposed to the chemical mutagen mitomycin C (MMC) at a dose which causes only a low frequency (0.07 per cell) of chromatid aberrations.

We have confirmed Latt's[12] finding and, since the FPG technique provides an easy, rapid and high resolution method for detecting SCE, investigated whether the induction of SCE could provide a simple and sensitive endpoint for assaying mutagenicity in mammalian cells. We now present some of our results obtained with a line of Chinese hamster fibroblasts (CHO) exposed *in vitro* to fifteen mutagens–carcinogens, each in a range of concentrations (doses). Our findings from these experiments, and from preliminary studies on patients treated with cytotoxic drugs, strongly suggest that the SCE test provides a powerful tool for *in vitro* mutagen testing and possibly for monitoring people exposed to known or suspected mutagens–carcinogens.

In all the *in vitro* experiments CHO cells were used and cultured as described previously[11]. Exponentially growing cells were exposed to 10 μM BUdr for two cycles of DNA replication before treatment with colcemid (2 h at 2×10^{-7} M), collection by mitotic shake-off[13], pretreatment for 7 min with 0.075 M KCl and fixation in 3 : 1 methanol–acetic acid. Throughout, all cultures were maintained in the dark or under a yellow safe light to minimise photolysis of BUdr and background SCE[8]. Air-dried preparations were made, stained by the FPG procedure[10] and coded and scored for SCE and chromosomal aberrations by one observer.

X rays

SCE were scored in "harlequin-stained" (Fig. 1) chromosomes at the first mitosis after acute (50 rad min^{-1}) X-ray exposures at various doses. Using synchronously developing cultures (see legend for Fig. 2), the responses of cells exposed in G_1, S and G_2 were determined (Fig. 2). The incorporation of BUdr into DNA enhances its sensitivity to damage by both X rays[14] and ultraviolet light[15]. In our experiments chromatids in G_1 cells were all unifilarly substituted with BUdr at the time of irradiation, whereas half of the G_2 chromatids were bifilarly substituted. Our data demonstrate, however, that the chromosomes in G_2 cells showed no increase in SCE over background at any of the doses, whereas there were significant dose-dependent increases in S and G_1 cells.

Studies on chromatid aberrations induced by certain chemical mutagens[16,17] have shown that cells exposed in G_2 do not yield aberrations at the ensuing mitosis, but do so at the subsequent division, the development of aberrations necessitating an intervening DNA replication between treatment and observation. Somewhat similar, but not identical, findings have also been reported with ultraviolet light[18,19]. With ionising radiations, however, irradiation of G_2 cells results in the formation of aberrations which are seen at the first mitosis after exposure, and although there is some evidence for a small increase in aberrations in irradiated G_2 cells at their second mitosis[19], it is clear that a large proportion of the lesions that develop into aberrations do so shortly after their formation without the need to pass through a replication phase. Our data on the X-ray induction of SCE, however, closely parallel those obtained for aberrations with ultraviolet light and many chemical mutagens, suggesting that the X-ray-induced lesions resulting in SCE are relatively long lived (and are presumably therefore not single strand breaks[20]), become manifest as SCE events as a consequence of DNA replication and reflect a type of recombinational repair process.

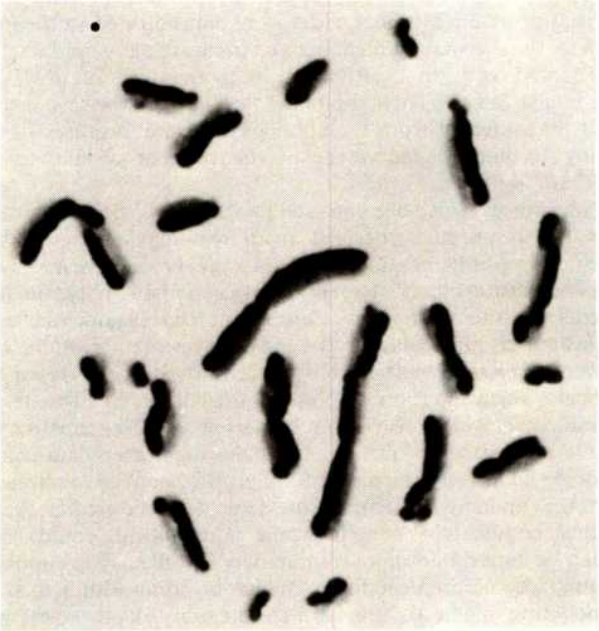

Fig. 1 M2 metaphase cell from a Chinese hamster cell line (CHO) after two rounds of replication in the presence of BUdr (10 μM) and stained with the FPG technique. Note the differentiation between chromatids and the presence of 12 SCEs.

In the context of this report, we emphasise that although there is a linear or curvilinear relationship between X-ray dose and SCE yield in G_1 and S cells, the increased incidence of SCE is minimal in relation to the induced incidence of chromosome and chromatid aberrations and this contrasts markedly with our results on chemical mutagens (see below). For example, at an X-ray dose which doubles the SCE incidence (~400 rad) there is a more than twentyfold increase in aberration frequency. This would imply that the induction of X rays of the kinds of lesions that result in SCE is inefficient relative to those events that result in aberrations, or, that most of these lesions are repaired (and a proportion gives rise to aberrations?) outside the S phase. In any case it seems clear that counting the incidence of SCE does not seem to provide a sensitive system for detecting X-ray exposure.

Chemical agents

The effectiveness of a chemical as a mutagen depends on various factors. Some mutagens are highly reactive with a short half life *in vivo* and may be very unstable in solution so that treatment with such agents, for example, sulphur mustard and to a lesser extent methyl and ethyl methane sulphonates (MMS and EMS) and N-methyl-N-nitro-N-nitrosoguanidine (MNNG), is essentially in the form of an acute or semi-acute exposure. Other mutagens, for example, mitomycin C (MMC), are much more stable and their continued presence effectively results in a chronic exposure. The activity of most agents is very dependent on *p*H and some, for example, cyclophosphamide, are not active *per se*, but are metabolised within the body to give mutagenic metabolites. Much human exposure to environmental chemical mutagens may be considered to be akin to a chronic exposure, so that in the present experiments all chemical agents were introduced into the culture medium at the time of addition of BUdr and the medium was not changed until the cells were sampled 24–36 h later.

Most of the agents selected for study were chemically unrelated, but all were proven (or suspected) mutagens or carcinogens. Many caused considerable delays in cell progression and these delays were assessed for each concentration of chemical in preliminary experiments in which mitotic cells were collected at various intervals after 24 h, and final sample times were then selected to give good yields of M_2 cells. Virtually all control cells sampled after 24 h were in the M_2 division, whereas with sub-lethal doses of many agents, samples collected as late as 36 h contained a high proportion of M_1 cells. These delayed M_1 cells showed a very high frequency of chromosomal aberrations compared with M_2 cells on the same slides (Table 1). It is important to realise therefore that cells scored for SCE at high concentrations represent selected samples which must give un underestimate of the maximum SCE frequency.

The chemical agents studied, and the relationship between initial dose (concentration) and SCE frequency in M_2 cells, are shown in Fig. 3. The alkylating agents, and in particular the bifunctional compounds—MMC and nitrogen mustard (HN_2, Fig. 4)—are extremely potent inducers of SCE in CHO cells, with MMC giving a doubling of SCE freqency at 10^{-8} M. The monofunctional alkylating agents, on the other hand, are generally less effective and show a considerable range in their ability to induce SCEs. This result is consistent with the finding that monofunctional agents are usually less efficient at inducing chromosomal aberrations than their bifunctional analogues[21]. Monofunctional compounds, however, may be more efficient in inducing mutations in bacteria and bacteriophage[21]. It is also notable that of the sulphonates, MMS is a more potent inducer of SCE than EMS, and this is also true for the induction of chromosomal aberrations. Thus, the ability of an alkylating agent to induce SCEs seems to bear no simple direct relationship to its efficiency in inducing point mutations in bacteria, but is more closely related to its ability to induce chromosomal aberrations in eukaryotes.

Quinacrine mustard (QM) produces chromosomal aberrations and is a monofunctional alkylating agent which may also intercalate between the bases in DNA[22]. Other intercalating agents produce frame shift mutations in bacteria as a consequence of distorting the double helix, and QM and the two other intercalating agents we studied, the anti-tumour[23] antibiotic adriamycin and the fluorochrome Hoechst 33258, a dibenzimidazol derivative[24], are also very effective inducers of SCE, with adriamycin being a very efficient inducer of chromosomal aberrations[25]. Chromosomal aberrations are also induced by the potent carcinogen[26] and mutagen[27] 4-nitro-quinoline 1-oxide (4NQO), which is also a very efficient inducer of SCE.

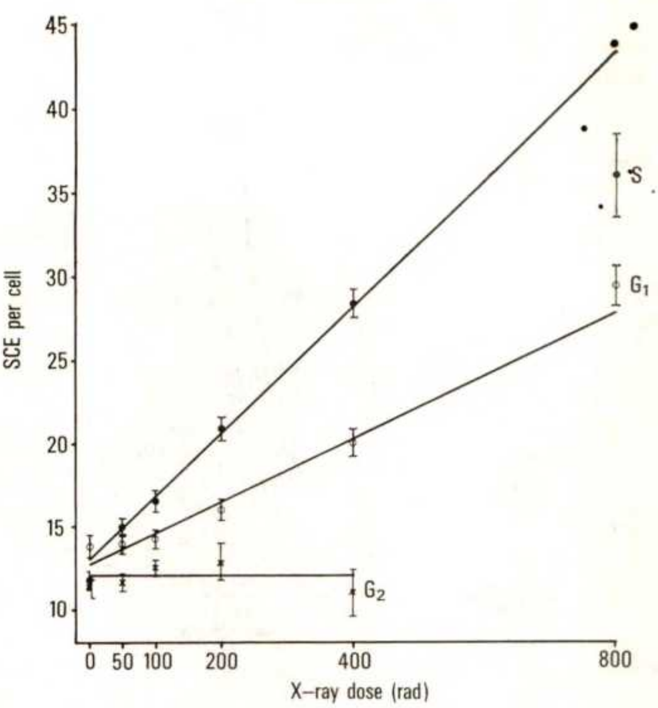

Fig. 2 The relationship between X-ray dose and SCE frequency in M_2 cells exposed to radiation in G_1 (○), S (●) and G_2 (×) of the second cell cycle. All irradiations were carried out on cells which had completed at least one round of replication in BUdr, using a Siemens Stabilipan X-ray set giving 50 rad min^{-1} at 250 kV and 15 mA after filtration with 0.8 mm Su, 0.25 mm Cu and 1 mm Al. Cells exposed in G_2 were treated with colcemid 90 min after exposure of asynchronously developing populations and collected by mitotic shake-off 2.5 h later. For G_1 and S exposures, cells were synchronised by mitotic shake-off after one cell cycle of culture in the presence of BUdr (11–12 h). Serial shake-offs were performed every 15 min and cell samples with a mitotic index ⩾ 98% were collected and pooled, on ice, to give sufficient cells for replating at 37 °C and irradiation. Cells were irradiated 90 min (G_1) or 7.5 h (S) after plating and cell stages were checked by autoradiography of parallel ^{3}H-thymidine labelled cultures. G_1 and S cells were maintained in BUdr medium and exposed to colcemid before collection 17 h and 13 h after irradiation. Sampling times were adjusted to take account of mitotic delay and SCEs were scored in metaphase cells with harlequin-stained chromosomes characteristic of cells completing two rounds of replication in the presence of BUdr (Fig. 1). The lines in the figure were drawn by eye and each point represents a mean ± s.e. from 50 cells.

Figure 3 shows that two of the fourteen chemical agents studied induced no SCE. Maleic hydrazide (MH), which is widely used as a herbicide, is a potent inducer of chromosomal aberrations in plant cells when applied in solution at low *p*H[28]. It has never been reported to cause chromosome damage in mammalian cells and in our experiments, where *p*H was maintained at 7.2 using HEPES buffer, it induced neither aberrations nor SCE. The other compound which had little effect on SCE was the antineoplastic[29] agent cyclophosphamide. In itself, cyclophosphamide is ineffective as a cytostatic or chromosome damaging drug, but it is metabolised in the liver to give a very active bifunctional alkylating intermediate[30]; its inefficiency in producing aberrations and SCE in our *in vitro* system is therefore hardly surprising.

Table 1 Frequencies of chromosome aberrations in 34-h samples of cells exposed to 10^{-7} M mitomycin C (50 cells per sample)

Treatment	Chromosome aberrations				Chromatid aberrations		
	Dicentrics	Rings	Deletions	Gaps/Breaks	Rings	Isochromatid	Interchanges
MMC only	1	1	—	1	—	4	5
MMC+BUdr M_2 cells only	—	6	—	—	2	—	4
MMC+BUdr M_1 cells only	1	4	1	7	1	2	9

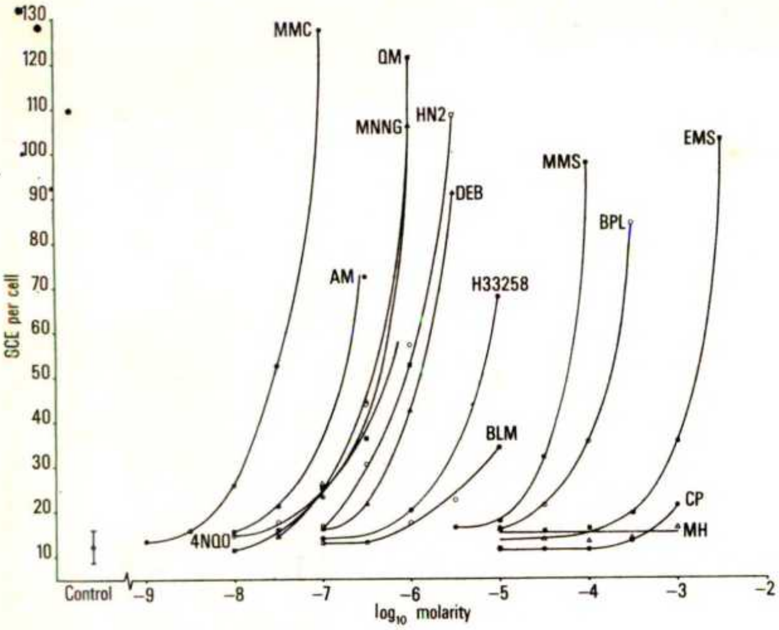

Fig. 3 Dose–response curves for SCE incidence in CHO cells against log of initial concentration of chemical agent, for the fourteen chemical agents studied. All chemicals were added to culture medium at the time of addition of BUdr and the medium was not changed until collection (see text). Those agents that were insoluble in water were first dissolved in a small volume of ethanol before dilution in tissue culture medium and all dispensing was completed in 8 min. Collection times were adjusted to take account of mitotic delay and cultures were maintained at 37 °C. SCEs were scored in harlequin-stained chromosomes of second division cells, and each point on the graph represents a mean frequency of SCE from 20 cells (~400 chromosomes); standard errors are not shown since for all points they were less than 5% of the mean frequency. MMC, Mitomycin C; AM, adriamycin; MNNG, N-methyl-N-nitro-N-nitrosoguanidine; QM, quinacrine mustard; 4NQO, 4-nitroquinoline 1-oxide; HN2, nitrogen mustard; DEB, diepoxy-butane; H33258, Hoechst 33258; BLM, bleomycin; MMS, methylmethane sulphonate; BPL, β-propriolactone; EMS, ethyl methane sulphonate; CP, cyclophosphamide; MH, maleic hydrazide.

All the tested agents which induce SCE also induce chromosomal aberrations, and an important practical question is whether these agents produce significant increases in SCE at doses which induce only a negligible or low aberration frequency. We have examined this question by scoring for aberrations at doses which give a doubling of SCE incidence, and for doses which result in a tenfold increase in SCE. The results are summarised in Table 2. In considering these data it must of course be remembered that SCE can only be scored in M_2 cells and, as already indicated (Table 1), the frequency of chromosomal aberrations is often higher in M_1 cells. Some of the aberrations were induced by the BUdr itself[31] (Table 1) and most of the chemical agents were found to induce chromatid-type changes. Most of the chromosome-type aberrations in the M_2 cells listed in Table 2 were "derived"[32] by duplication from chromatid-type aberrations produced in the first cell cycle. The data in Table 2 show that for all but one (bleomycin) of the twelve mutagens–carcinogens studied, a dose of mutagen that gives a highly significant doubling of the incidence of SCE produces only a minimal and, with the small number of cells scored, barely noticeable effect on the incidence of chromosomal aberrations. Doses giving tenfold increases in SCE gave increased, but still very low, aberration frequencies.

The scoring of chromosomal aberrations requires a high

Table 2 Total chromosomal aberration frequency and total SCE in 20 M_2 cells scored at each of two doses for each chemical agent

Chemical	Chromosome aberrations (B″)			Chromatid aberrations (B′)				Total B″+B′	Total SCE
	Dicentrics	Rings	Deletions	Gaps/breaks	Rings	Isochromatid	Interchanges		
Control									
BUdr only	1	1		1				3	244
AM 3×10^{-8} M				1		1		2	430
3×10^{-7} M				++	++	++	++	++	1,444
EMS 3×10^{-4} M		2	2					4	382
3×10^{-3} M			1	1			1	3	2,054
MMS 3×10^{-5} M		1						1	644
3×10^{-4} M		1						1	1,952
MMC 10^{-8} M		2	3	1				6	512
10^{-7} M								0	2,555
HN_2 3×10^{-7} M								0	612
3×10^{-6} M		2				1		3	2,175
4NQO 10^{-7} M								0	462
10^{-6} M			1					1	1,140
MNNG 10^{-7} M		1	2					3	528
10^{-6} M		4		3	2		3	12	2,124
DEB 3×10^{-7} M			1			1		2	403
3×10^{-6} M		4						4	1,818
BLM 3×10^{-6} M				++	++	++	++	++	451
—	—	—	—	—	—	—	—	—	—
QM 10^{-7} M								0	506
10^{-6} M		1	4					5	2,422
CP 10^{-3} M		1	1					2	424
—	—	—	—	—	—	—	—	—	—
BPL 3×10^{-5} M		2						2	425
3×10^{-4} M		3	1				1	5	1,668

The two doses selected were those which resulted in an approximate doubling and an approximate tenfold increase in SCE. With all agents except bleomycin, a doubling dose for SCE resulted in no obvious increase in chromosomal aberrations in the M_2 cells scored, and, in most cases, a dose giving a tenfold increase in SCE gave only a very much smaller increase in chromosomal aberrations. With both bleomycin and adriamycin at 3×10^{-7} M, there were too many chromatid-type aberrations present for accurate scoring, and this is indicated by ++.

level of skill and is very time consuming, since even at fairly high doses of mutagen the analysis of up to 100 cells or so per dose, which may involve several hours at the microscope, may be necessary to obtain significant results. Our findings show that through determining SCE frequencies it is possible to detect significant effects of mutagens on chromosome structure at doses that are usually very much lower than those necessary to produce marked increases in chromosomal aberrations. Moreover, the scoring of SCEs requires little training and is extremely rapid, so that, for example, the detection of a doubling of background incidence, at the 5% level of significance, requires the scoring of no more than 10–20 cells, which takes a matter of a few minutes.

In vivo studies on man

We have shown[33] that the incidence of SCE in human blood lymphocytes is relatively constant between individuals, and is independent of age and sex. The notable exception here is the very high SCE incidence in cultured cells from patients with Bloom's syndrome[34], an increase which is not evident in cells from patients with other inherited chromosome instability syndromes[33,34]. This stability, and the very high sensitivity of what we have referred to as the SCE test, has therefore led us to look for increases in SCE frequencies in peripheral blood lymphocyte chromosomes of patients undergoing therapy with cytotoxic drugs. Only preliminary results are available and our detailed findings will be presented elsewhere. But it is clear from our first results on patients treated with adriamycin that significant increases in SCE are to be observed in blood cells sampled 24 h after injection with this drug, at dose levels which produce only a negligible frequency of chromosomal aberrations in these cells. It seems possible therefore that we may be able to use SCE incidence to detect significant exposures of individuals to mutagens–carcinogens.

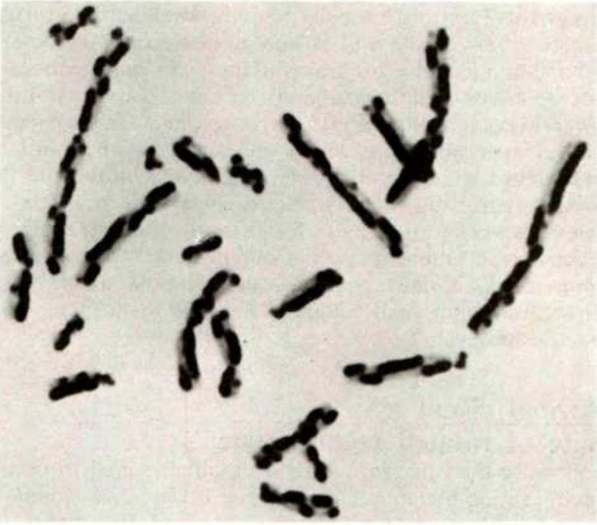

Fig. 4 M2 CHO cell after exposure to BUdr and HN_2 (3×10^{-6} M) throughout the two cell cycles before sampling. Note the approximately tenfold increase in SCE relative to the example from controls in Fig. 1.

Implications and applications

Our results show that the marked increase in incidence of SCE in cells exposed to a wide variety of chemical mutagens is associated with very much smaller increases in chromosome aberration yields, whereas the converse holds in cells exposed to X radiation. Chromosomal aberrations are of course mutational events, although many will be expressed as dominant lethals in germ cells. A very relevant question therefore is whether SCE events are themselves associated with mutational changes? This question is difficult to answer, but we believe that at least some sister chromatid exchanges may be associated with mutation. Our reasons for this belief are based on two arguments. First, SCE is often seen to have occurred at the site of chromatid breakage, or intrachange resulting in duplication and/or deletion. It is evident therefore that incomplete or abnormal SCE events do occur, and that these certainly result in aberrations and mutations. Second, the exchange event that results in SCE involves recombination between parent and daughter polynucleotide strands at sites of transient discontinuity in both parental strands[11]. Our data suggest that this recombination repair process[36] takes place at the time of DNA replication and it seems not improbable, as has been demonstrated in bacteria[37] and meiotic cells of yeast[38], that mutation originates as an error in the recombination repair process following mispairing and base deletion or insertion.

Our data show that SCE frequencies are far more sensitive indices of chromosome damage than frequencies of gross chromosomal aberrations, and that the new techniques to detect them have provided a simple, reliable and highly sensitive method for assaying the chromosome mutagenicity of environmental agents. Only further work will establish whether these techniques will provide a good system for monitoring human exposure, but we suggest that the *in vitro* SCE test on human or other mammalian cells should form part of any environmental mutagen testing programme.

Polarity of structure and of ordered nerve connections in the developing amphibian brain

Shin-Ho Chung & Jonathan Cooke

National Institute for Medical Research, London NW7 1AA, UK

Tectal polarity for retinal connections remains reversible long after the anatomical pattern of neural structures has been determined. Cells in the diencephalon seem to control this polarity. Following certain embryonic operations, the diencephalon developed behind the tectum. In such cases, the polarity of the retino-tectal projection was reversed.

THE amphibian retino-tectal projection has been widely used for studying the mechanisms governing selective nerve connections. One important fact which has emerged from the study of this system is that critical events occuring early in ontogeny determine the axial polarity of the retina with respect to its connections to the tectum, the primary visual centre. When an eye in a stage 32 *Xenopus*[1] is rotated by 180°, cells in the original anterior pole of the retina connect to the posterior pole of the tectum, as they would have done if left undisturbed, and the animal's visual world is accordingly rotated by 180°. If a similar operation is performed some 7 h earlier (Stage 28 in *Xenopus*), the animal develops normal visuo-tectal connections[2-5], because of repolarisation of the eye in the orbit.

It has been conjectured[6] that an equivalent determination of axial polarity occurs within the tectum, to which retinal cells later connect through their optic nerve fibres. The time of tectal polarisation is not known, for the only attempted rotation experiments on the tectum comparable with those on the embryonic eye did not give clear results[7]. If such tectal polarisation does take place, it is likely that the information for this, whatever its nature, may originate from a local group of cells, as has been demonstrated for the control of spatial patterns of cellular differentiation early in embryonic development[8,9].

Here we report briefly on the results of an investigation directed at these questions. Our findings indicate that such polarising information can originate from a group of cells outside the tectum, namely, those which are subsequently to form the diencephalon. They also suggest that tectal cells do not acquire permanent positional labels before optic innervation. Detailed reports, including autoradiographic studies of histogenesis and electrophysiological evidence for the presence of normal synapses in rotated tecta, will be presented elsewhere.

Embryonic operation

The presumptive midbrain regions of 83 embryonic *Xenopus* were cut out and replaced after rotation by 180°. Most of the operations were carried out at stages 21–24, or approximately 22–26 h after fertilisation, with some at stage 37, some 24 h before the optic nerve reaches the tectum[10,11]. No differentiation is detectable among cells of the neural tube until midway between these two periods, but earlier work on another species[12] has shown that even well before stage 20 the neural rudiment is a mosaic of regions, each with a strong tendency to develop into a particular part of the brain. We confirmed that this situation obtains also in *Xenopus* by examining embryonic brains following rotation of small pieces in neural plate stages. The dorsal diencephalon (thalamus) and adjoining optic tecta develop from a dorsal section, some 15 to 20 cells square as counted directly through the dissecting microscope, of the stage 22 neural tube (Fig. 1). By varying the anterior–posterior levels of the cuts, but attempting to rotate in each case a similar sized piece, we were able to produce brains with different spatial arangements of these anatomical parts.

Owing to elastic forces resulting from morphogenetic movements and cellular differentiation, the operation on the brain rudiment of stage 37 larvae is difficult. Nevertheless, we have succeeded in mapping two animals after rotating tectal structure at this stage.

We used several criteria for assessing operations as successful. First, we checked visually whether the cut tissue remained in place 48 h after operation. Second, we observed gross derangements of brain anatomy in cases where the rotated tissue had healed properly, and confirmed this in serial histological sections. Finally, when we carried out control experiments in which the cut piece of neural tube was discarded, we observed two classes of results from those animals surviving until metamorphosis. In one class of animals, regeneration had given rise to brain structure and retino-tectal connections indistinguishable from those of unoperated animals, and the other showed atectal brains with forebrain grossly enlarged and the diencephalon joining the brainstem.

Normal visual map in spite of rotated tectal tissue

Following the operation, only 10 animals failed to establish good retino-tectal connections. From the remaining animals, 63 electrophysiological maps of the direct optic projection to the contralateral tecta were obtained during metamorphic climax, using procedures detailed elsewhere[10]. For clarity, only one or two of the several rows of electrode positions plotted are shown for each map presented here. The brains and their associated maps fell into three main categories, which we now discuss in turn.

A parasagittal section of the normal brain is shown in Fig. 2*a*. The diencephalon (D) is seen immediately in front of the midbrain, with its single tectum (T). Figure 2*b* shows a comparable section of a brain where we believe the anterior part of the tectal precursor had been rotated. Viewed from the dorsal surface, a pair of tecta were clearly identifiable on each side, separated by the indentation and blood vessels seen at the tecto-diencephalic junction in the normal animal. In brain sections of such animals, tectal histogenesis can often be seen to progress from this new junction, forwards in anterior tectum and backwards, as normally[10], in the posterior. As the recording electrode was moved successively backward from the anterior pole of the anterior tectum to the posterior pole of the posterior tectum, positions in the visual field from which electrical responses could be evoked also shifted from the anterior pole to the posterior pole. Note that, throughout, we use the terms anterior and posterior in relation to the animal's present body axis, rather than any original polarity of tissue in the embryo. Figure 3*a* shows the visuo-tectal map obtained from one such animal, a histological section of which is exhibited in Fig. 2*b*. Similar anatomy and map were observed from two animals whose tectal rudiment had been rotated at stage 37 (Fig. 3*b*). Thus the array of retinal fibres ignores the anatomical consequences of operation to produce a normal, single map with respect to the visual field and animal's body axis, by distributing itself across the two tecta. We therefore conclude that tectal tissue itself, rather than having assumed a fixed axial polarity for selective nerve connections, remains subject to overriding influences from outside the tectum until at least some 13 h after the equivalent retinal polarity is irrevocably determined[2–5].

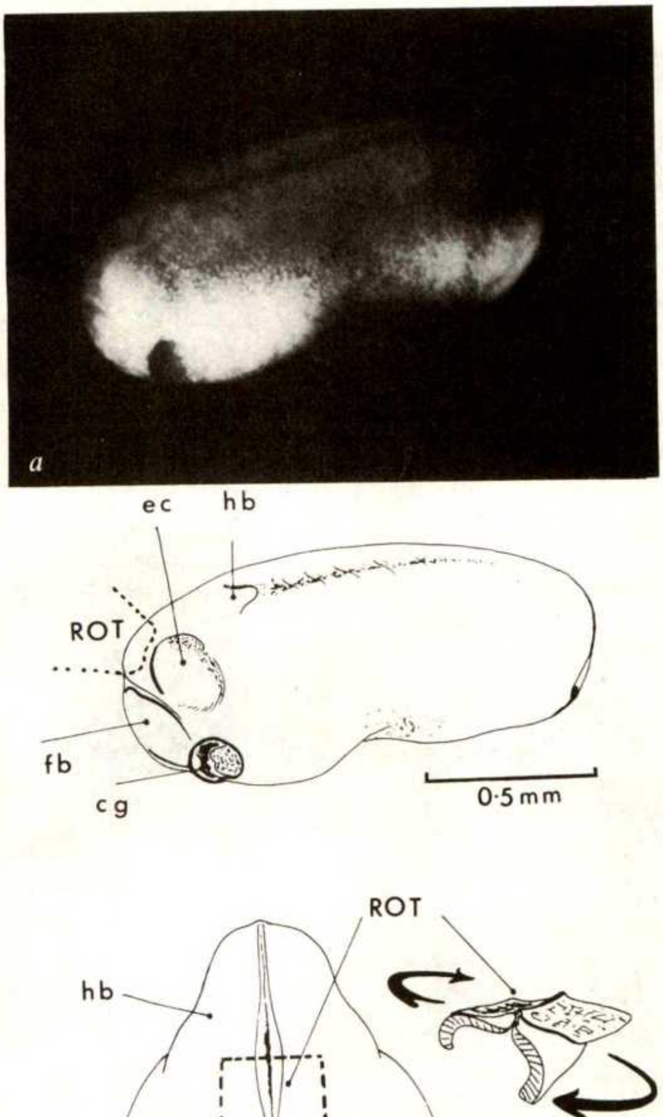

Fig. 1 Embryonic operation. *a*, Photomicrograph and *camera lucida* drawing of a stage 24 *Xenopus* embryo. Embryos were staged according to the tables of Nieuwkoop and Faber[1]. Operations were performed with sharpened tungsten needles and hair loop, in two-thirds strength Niu Twitty solution brought to *p*H 7.1 with diluted HCl. On the drawings, the heavy dashed line marks the limits of tissue reversed in a typical operation. *b*, Drawing of the head from anterior–dorsal aspect at stage 24. ec, Eyecup; hb, hind-brain; cg, cement gland; fb, forebrain vesicle; ROT, rotated piece of neural tube and overlying epidermis.

In many animals of the present category, particularly those where the new junctional groove and blood vessels were conspicuous between the anterior and posterior tecta, the path of the optic nerve was altered. Instead of entering the tectum at its anterior border[13], the optic nerve now invaded both tecta from the position of the new intervening groove. Evidence for this is threefold. First, massive responses with large receptive fields were obtained at the junction point, instead of at anterior poles of both tectum and visual field as in normal animals[10]. Second, we observed instances in which both the anterior pole of the anterior tectum and posterior pole of the posterior one were electrically silent. Finally, histological preparations of certain animals clearly show ascent of fibres between the two tecta. We therefore believe that factors normally guiding these fibres to the tectum are distinctive to the diencephalon –midbrain junction, which has been transferred posteriorly in these operations. Regardless of the trajectory of the optic nerve, incoming fibres treated the two tecta as one and distributed themselves with correct order and polarity, thereby showing that control of the direction of innervation and of progressive tectal differentiation are quite independent of the polarity of the visuo-tectal map.

Reversal of visual maps related to position of diencephalon

When the positions of cuts, at operation, were brought forward by only some 5–10 cells in the neural tube, the diencephalic structure (epithalamus, thalamus and hypothalamus) developed behind the tectum, rather than in front (Fig. 4*a* and *b*). Thus a small group of precursor cells, at stage 24, are determined as diencephalic; they form the diencephalon even when moved to a position adjacent to hind-brain precursor cells. The anterior pole of the tectum in such animals was joined directly to the telencephalon, whereas normally the diencephalon is interposed between these two structures (compare Fig. 4*a* and *b*). A typical visuo-tectal map obtained from one such animal is shown in Fig. 4*c*. In contrast to a normal map, the anterior visual field was now represented in the posterior pole of the tectum, and the posterior in the anterior pole; the visuo-tectal map was completely reversed.

The medio–lateral polarity, unlike the anterior–posterior one, was not reversed. As in normal animals, fibres stemming from the ventral part of the retina (namely, those subserving the superior visual field, as the lens inverts the image) positioned themselves more medially than those from the dorsal retina. Because the original operation was symmetrical about the animal's midline, we do not expect, and indeed have never found, any reversal in the medio–lateral axis of maps.

Following the version of the operation just discussed, 13 animals developed two separate tecta on each side, separated by the diencephalon (Fig. 5*a*). This presumably occurred because of inevitable variability in the operation, whereby in these cases some tectal precursor tissue had been left unrotated posteriorly.

A parasagittal section of such an animal shows clearly that the infundaibular recess and hypothalamic nuclei lie directly below the level at which the two tecta join, and the cellular mass constituting the dorsal and ventral thalamic nuclei is interposed between the tecta (Fig. 5*a*). In trans-

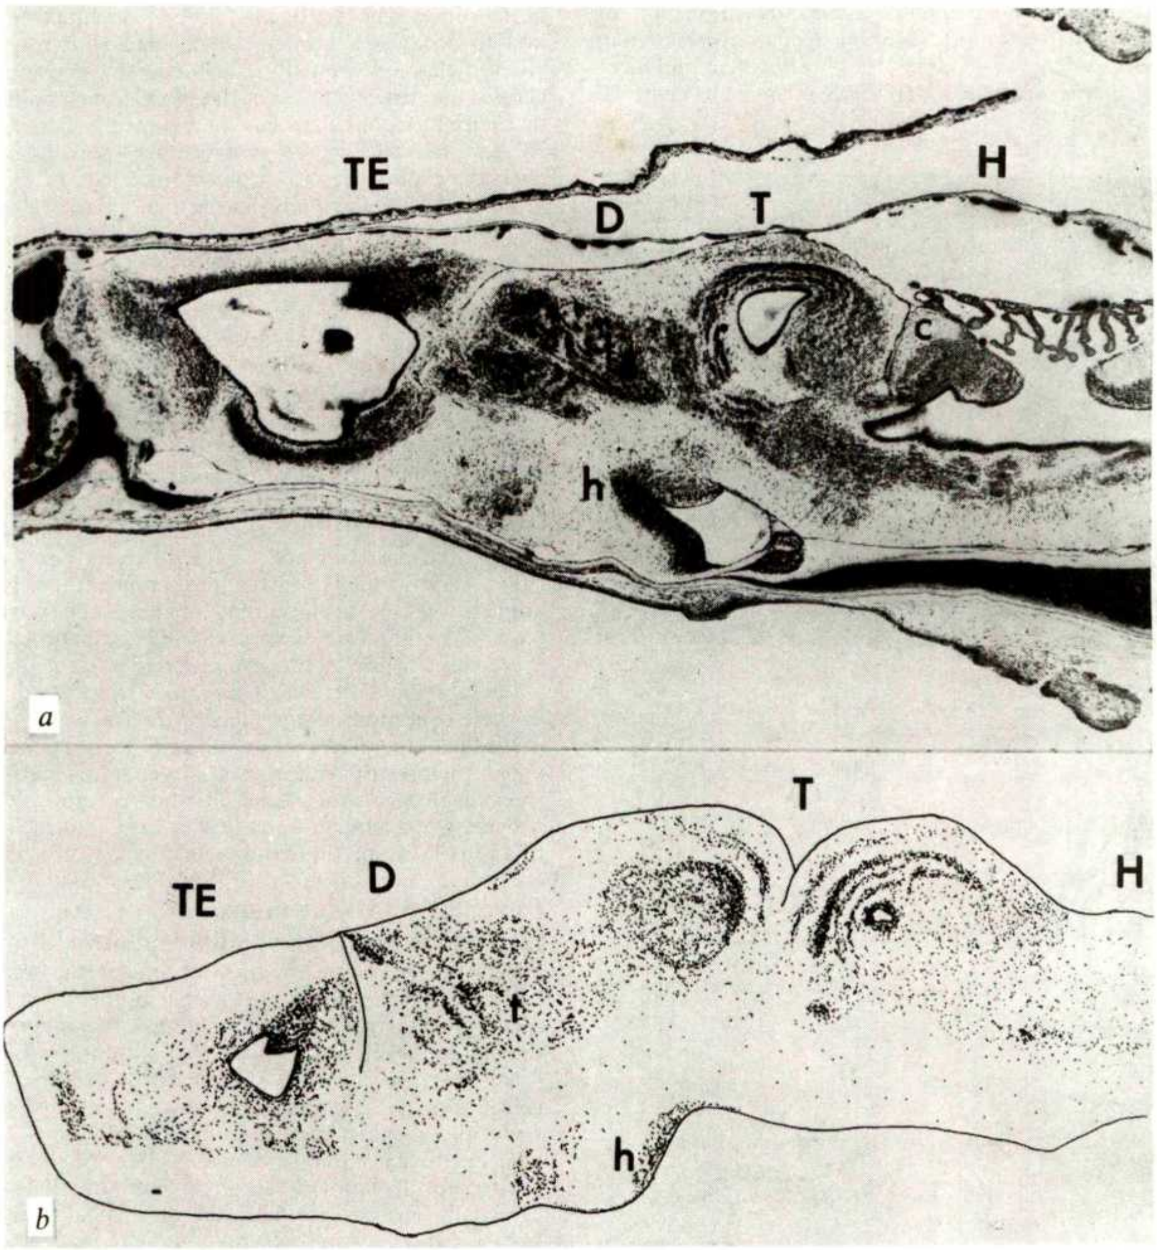

Fig. 2 Parasagittal sections of brains from (*a*) normal and (*b*) experimental tadpoles at stage 66. To make the rearranged structures more apparent, we have selected parasagittal sections throughout, although detailed anatomy is best followed in serial transverse sections. Because the experimental (*b*) animal was one also treated for ^{3}H-autoradiography, a *camera lucida* drawing is given since the visual appearance of the tectum is not comparable with the control (*a*) or with subsequent sections shown. TE, Telencephalon; D, diencephalon; T, tectum; H, hind-brain; h, hypothalamic nuclei; t, thalamus; c, cerebellum.

verse sections, not shown here, different diencephalic nuclei, including those of the epithalamus, can be identified more clearly. The pattern of visuo-tectal map in these animals showed that a complete visual field was represented in each tectum. The polarity of the map in the anterior tectum was reversed, whereas that of the posterior tectum was normal (Fig. 5*b*). Thus, the population of incoming fibres distributed themselves across the two tecta, those originating from the posterior part of the retina occupying, as in the normal brain, that tectal tissue adjacent to diencephalon.

In several animals, an extra diencephalon developed anterior to the tecta, in addition to the one between the two tecta. Embryologically, such an anomaly would be expected if some diencephalic cells were left *in situ* and some were translocated, and both groups then regulated to give complete structures. The anterior tectum, situated between the two diencephalons, showed two superimposed maps with opposing polarity, as illustrated in Fig. 6. When the recording electrode was at the most anterior pole of this tectum, responses could be elicited both from the far anterior and far posterior parts of the visual field. Similar responses could be obtained from the posterior pole of this tectum. Two ordered series of symmetrical pairs of responses were then obtained as the electrode positions advanced along the intervening tectum. Such overlapping projections of opposing polarity indicate that each diencephalon can exert its own polarising influence on the intervening tectum, independently of the other.

Implications for selective nerve connections

Several inferences can be made from our study about the mechanisms governing formation of selective nerve connections. The most general conclusion we can draw from our findings, without recourse to any specific notions previously advanced, is that polarity for selective nerve connections within tissues remains labile long after that for the anatomical pattern of the brain as a whole is fixed. The possibility remains, however, that the same positional

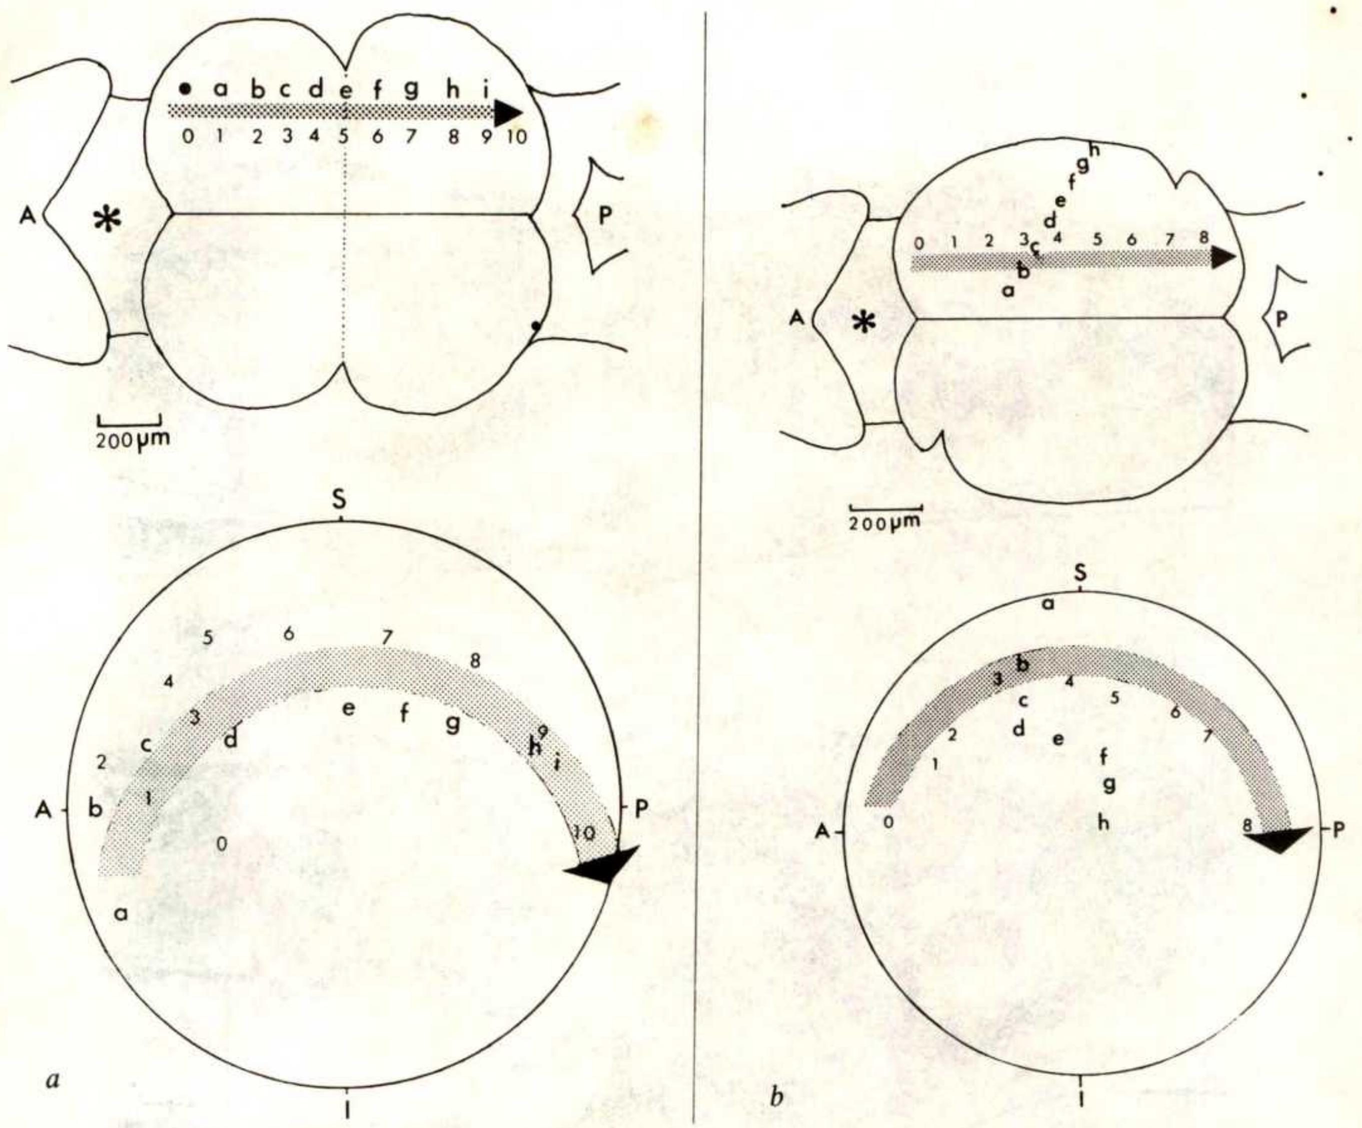

Fig. 3 Normal visual map after rotation of *a*, neural tube at stage 24 and *b*, tectal rudiment at stage 37. The map (*a*) was obtained from the animal whose histological section is displayed in Fig. 2*b*. All animals discussed in this paper were mapped between stages 62 and 66. Many rows of electrode positions were tested, but for the sake of simplicity, we show in this and following figures the results for only one or two rows. Positions in particular rows are either numbered or lettered consecutively, and positions in the visual field from which responses were obtained are then shown. Overall polarity of rows is shown for quick inspection by broad shaded arrows. Asterisks indicate the location of the diencephalic structure. A, Anterior; P, posterior; S, superior; I, inferior.

signal[9] is involved first in morphological determination and subsequently in establishing axial reference for selective nerve connections. The nature of such signals and of the cellular responses to them remain unknown. Nevertheless, our findings provide a basis for experimental attack on these problems in developing nervous systems.

Our results also suggest that a group of cells other than the tectal precursors can organise axial information within the developing tectum for incoming optic nerve fibres. These cells appear to be some or all of those which are determined to form the diencephalic structure itself. This conclusion is strengthened by results of the first category of animals (Figs 2, 3 and 4). Polarity of visuo-tectal maps in these animals was normal, although tissue normally situated at the very junction of diencephalon and tectum had been transferred posteriorly. The diencephalon thus may act in a way quite analogous to an embryonic organiser, in that each of them controls an axial polarity in surrounding tissue. In the case of the diencephalon, the polarity is that for the retino-tectal connections. Classical organisers, on the other hand, control anatomical patterns of cellular differentiation in surrounding embryonic tissues[9,14,15]. It is relevant to note here that the organiser for the axial pattern of the whole body during amphibian development is a small group of cells at the dorsal lip of the blastopore, which later form the anterior mesoderm[8,14,15]. This mesoderm then induces in overlying ectoderm the formation of the forebrain rudiment, of which the diencephalon is the central part. An obvious test for the hypothesis of diencephalic organiser is to transplant a presumptive diencephalon alone as a graft behind the presumptive tectum of the host. Our preliminary results from a series of such animals are conforming with our expectation.

Several models have been proposed for the formation of ordered retino-tectal connections during development[8,16–18]. Before trying to evaluate these models, one has to ask a fundamental question: how much information is encoded in each tectal cell? Maximum information is assigned to each tectal cell if each possesses a uniquely labelled positional code[6]. On the other hand, the minimum possible information is assigned to the tectum if there is only one reference point within or outside it, to align properly the projection of incoming fibres, and no positional memory is encoded in individual tectal cells[16].

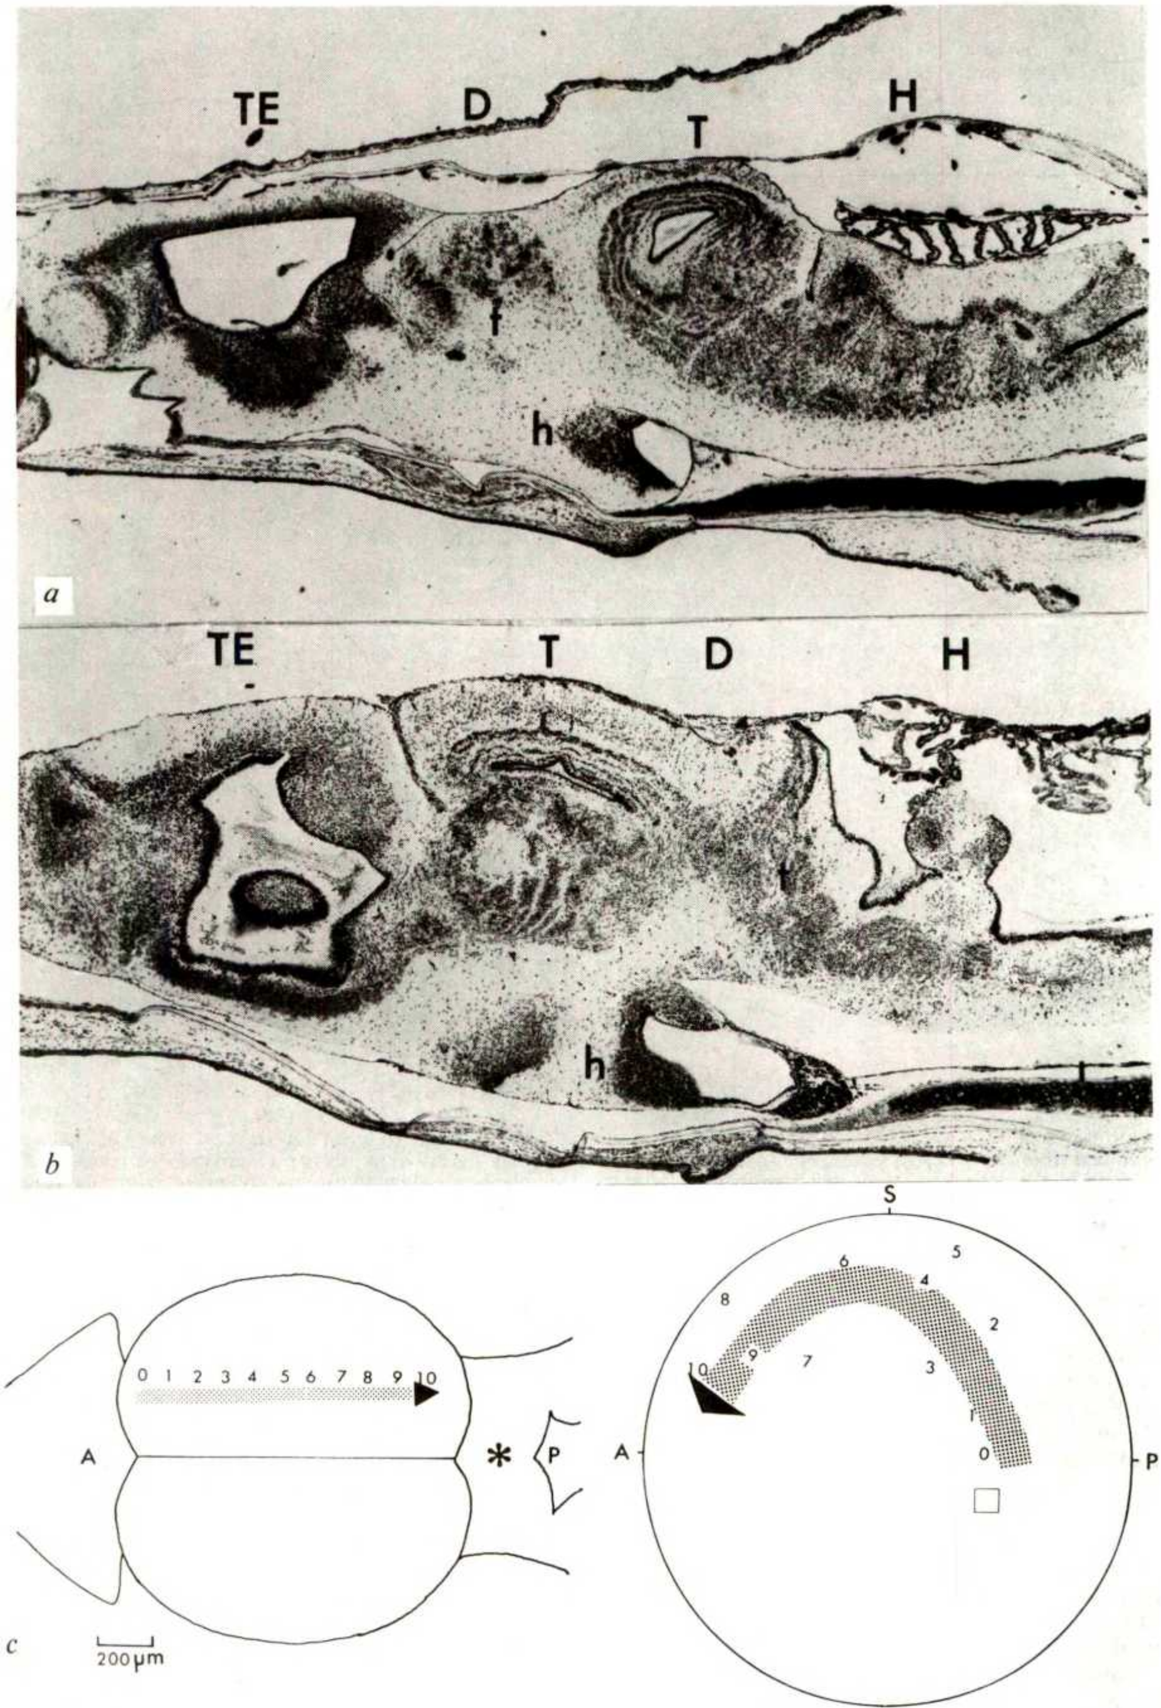

Fig. 4 Reversed visual map with diencephalon situated behind the tectum. Comparable parasagittal sections of *a*, normal and *b*, experimental animal (operated at stage 24). *c*, Reversed visuo-tectal map across the single tectum. The map and the histological section (*b*) were obtained from the same animal. From the electrode positions 2, 3, 4, 5, 6 and 8, responses could also be elicited by stimulating the visual field marked by the square. We can offer no plausible explanation for this anomaly. See Figs 2 and 3 for legend and abbreviations.

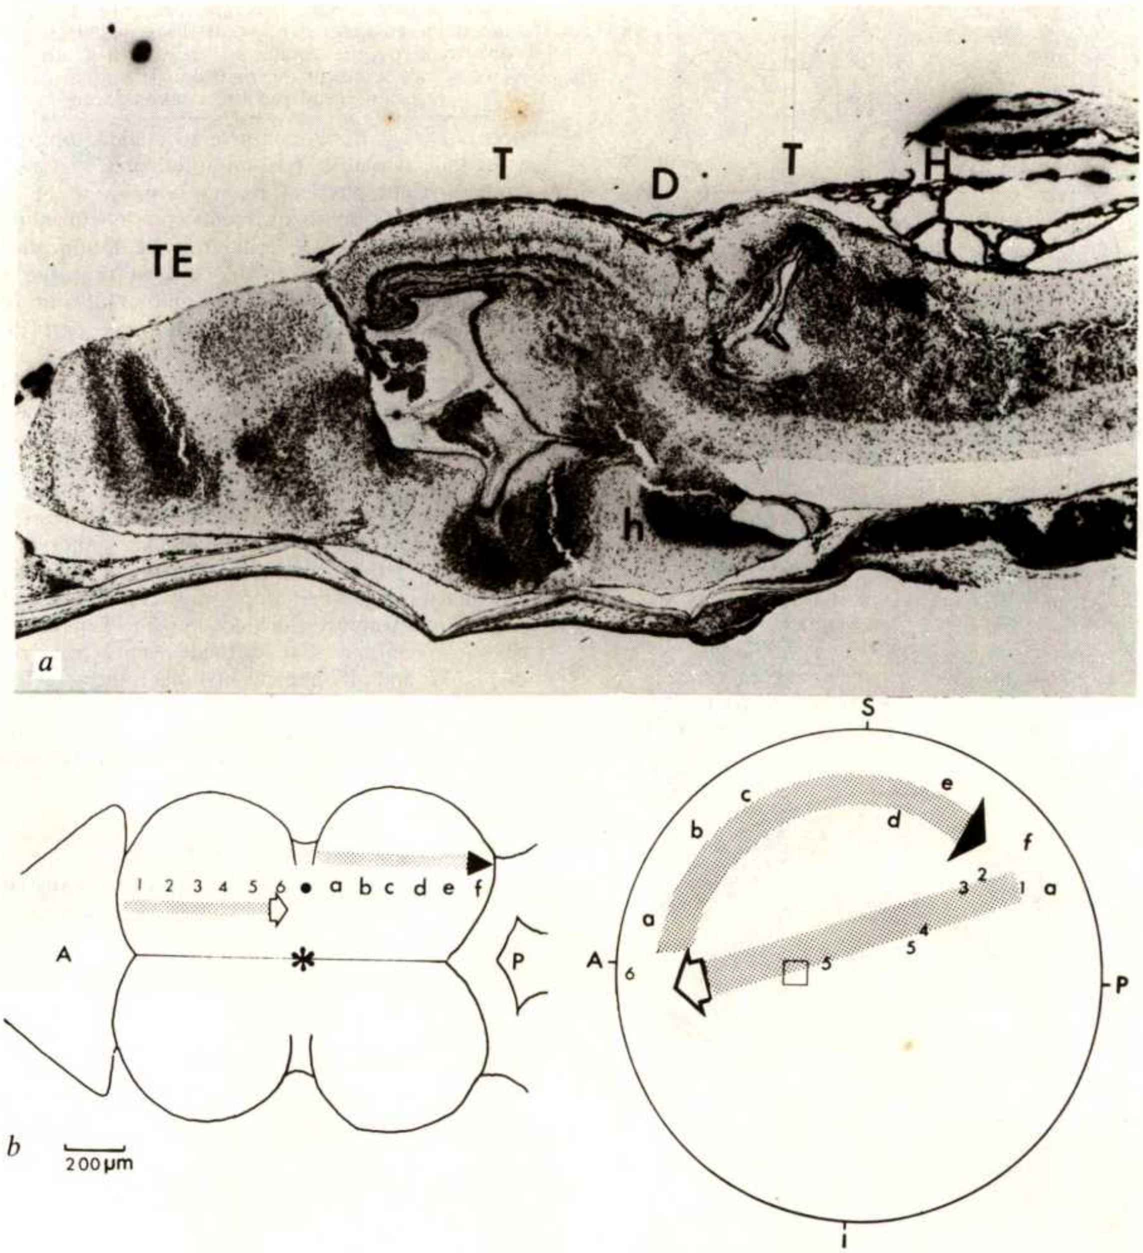

Fig. 5 Transposition of the diencephalon to lie between anterior and posterior tecta (operation at stage 24). *a*, Parasagittal section. *b*, Visuo-tectal map showing complete reversal for the anterior tectum and normal representation in the posterior tectum. The map and the histological section were obtained from the same animal. From the electrode positions 2, 4 and 6, responses could also be elicited by stimulating the visual field indicated by the square. See Figs 2 and 3 for legend and abbreviations.

Our present results show that positional labelling within tectal cells, if such ever occurs, can be overridden at least until stage 37 (Fig. 3*b*). Since functioning synapses are present by stage 45 in normal tadpoles[19], any positional labels having significance in ordering connections must have been acquired within the intervening period. Because the tectal rudiment at such stages is fragile and sticky, we have not succeeded in eliminating this possibility. The observation of dual projection patterns with opposed polarity (Fig. 6), across the same tissue, nevertheless makes it difficult to suppose that tectal cells possess unique labels before optic innervation.

Our results are equally consistent with a theory which requires no positional memory in tectal cells. If we assume that, in addition to a reference point in the nervous system, there is a mechanism whereby optic nerve fibres can preserve, on the tectum, the spatial contiguity of their origin in the retina, a wide range of experimental data including ours can be accounted for. The idea that mechanisms other than graded chemical labelling may be used by the nervous system in maintaining spatial contiguity, has been advanced previously. Lettvin's notion (cited in Chung[18]), for instance, is based on the fact that dendritic trees of retinal ganglion cells arborize extensively and interdigitate with neighbouring ones. Two fibres arising from adjoining retinal ganglion cells are, therefore, likely to exhibit a temporal contiguity in their discharge patterns, and such a coincidence in firing can, in principle at least, be used for maintaining spatial relations between the fibres. An alternative notion, advanced by Goodwin and Cohen[20], makes use of a signalling system arising from oscillatory metabolic processes in assigning positional codes to retinal and tectal elements, which then match up. In both of these models, each tectal element need not be uniquely labelled in order to establish ordered connections with retinal fibres. An underlying assumption in these

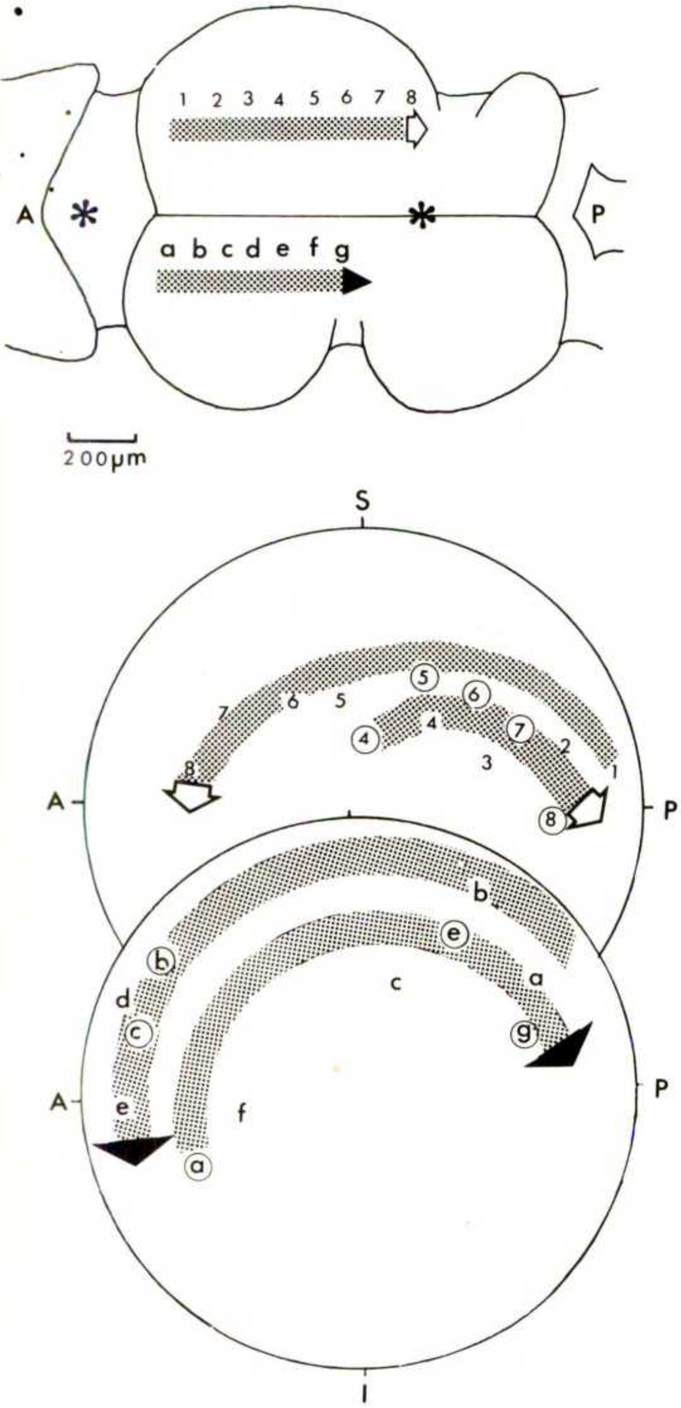

Fig. 6 Visuo-tectal maps obtained from tecta lying between 2 sets of diencephalic structure (operation at stage 24). Two superimposed ordered maps of the visual field with opposed polarity across the tectum, are seen on each side of the brain. Two circles represent the right and left visual fields. See text. For legend and abbreviations, see Fig. 3.

models is that fibres compete to achieve optimal matching with the available post-synaptic sites[17,18]. Whether such models reflect physical reality remains to be investigated.

Experiments involving tectal rotation in adult *Xenopus*[21] and goldfish[22,23] as well as transplantation studies on the *Rana catesbiana* tectum[24,25], suggest that the situation in the adult brain may differ from that during development. For instance, when tissues from one part of the adult tectum were interchanged with those from another part, they appeared to retain memory of their previous position in 13 cases[25], whereas no such information was retained in 14 other cases[24]. The conditions in which these two occur must first be ascertained.

A final evaluation of the two classes of theory we have outlined must, however, await further investigations. We propose that before tectal cells are innervated by optic nerve fibres, they possess no positional memory, and axial information for incoming optic fibres originates from a polarising structure located in the diencephalon. It can be shown either that critical events occurring between stages 37 and 45 irrevocably label tectal cells, or that a properly aligned map can be established in a developing tectum *in vitro* without diencephalic tissue, then our theory, in its simplest form, will have proved to be wrong.

We thank M. L. Errington and S. J. Caidan for technical assistance.

letters to nature

Radio galaxies and local quasars

A RECENT discovery regarding Centaurus A (NGC5128)[1] may have an important bearing on the very local quasar model (see for example, refs 2 to 5). These observers, using the new 4-m telescope at Cerro Tololo Observatory, have obtained remarkable photographs showing visible filaments extending away radially from the galactic centre and blue starlike images never before seen near the Galaxy. These starlike objects might have been called quasi-stellar had this term not taken on additional connotations since 1963, and this name may indeed be the proper one.

Such blue stars, presumably ejected from the galactic centre, are just what the very local quasar model predicts. They have been found in the area of the north-east radio lobe of Cen A at a distance of perhaps 80,000 light yr from the centre of that galaxy. If they have brightness similar to Type O stars, roughly 10,000 times brighter than the

Sun, they would appear as twelfth-magnitude stars as observed from the centre of NGC5128. Thus, to hypothetical astronomers in that galaxy, they would appear a little brighter than the quasar 3C273 as seen from Earth. These starlike objects near NGC5128 would then be of magnitude 23 or 24 as observed here, near the limit of observation.

If these blue stars are radio sources, as seems quite possible because of their location in the radio lobe, they could be producing radio emission by the same mechanism postulated for very local quasars[2–5], that is, by relativistic motion through the gas and magnetic fields near the galaxy which ejected them. This would produce synchrotön radio emission in great strength and over a long time, drawing its power from the kinetic energy of the relativistically-moving star. It will be of considerable interest for radio astronomers to determine whether these blue objects are indeed radio sources.

In any case, the radio emission is coming from their vicinity, and the radio output and blueness give them some of the properties expected of local quasars—local to the galaxy NGC5128. If these objects are moving with relativistic speeds their proper motions would be ~ 0.01″ yr^{-1}, and might just be observable over a number of years. Spectroscopy to determine the presence of a redshift or a blueshift would be very difficult, if not impossible, at this magnitude—near the limit of observation. Fluctuations in the optical and radio brightness would, however, be expected if these objects are indeed quasars local to Cen A, and should be looked for.

The energy required by the powerful radio emission from galaxies such as Cyg A and Cen A, which have strong emission from regions hundreds of thousands of light-years from the galactic centre, has been as much of a problem to explain as the energy source of quasars if cosmologically distant. Thus it may well be necessary to postulate the existence of very local quasars, massive objects thrown out (whether before or after condensation) from a gravitational collapse at the centre of a galaxy, in order to account for the puzzling properties of radio galaxies[2–5]. To inhabitants of those galaxies they would look much the same as quasars look to us, so that the explanation may well be the same in both cases.

Λ-type doubling in SiH molecule

In recent years there has been much interest in the detection of the radio-frequency spectra of interstellar molecules. The observed spectra of the molecules OH and CH corresponded to transitions between the Λ-doubling components of the lower rotational levels. While experimental determinations proved very difficult, theoretical calculations on the Λ doubling in the lowest rotational level of CH have been notably successful[1,2]. If the radioastronomical observation[3] is corrected for the epicentre and the calculated value for centrifugal distortion, then the agreement of theory and experiment for the radio-astronomical frequency is within 2 MHz in over 3,000 MHz.

SiH is similarly of interest as a probable interstellar species, but in this case the only available prediction for the radio-astronomical frequency band must be made by extrapolating Λ-doubling from high rotational levels populated in laboratory experiments to low rotational levels.[4]

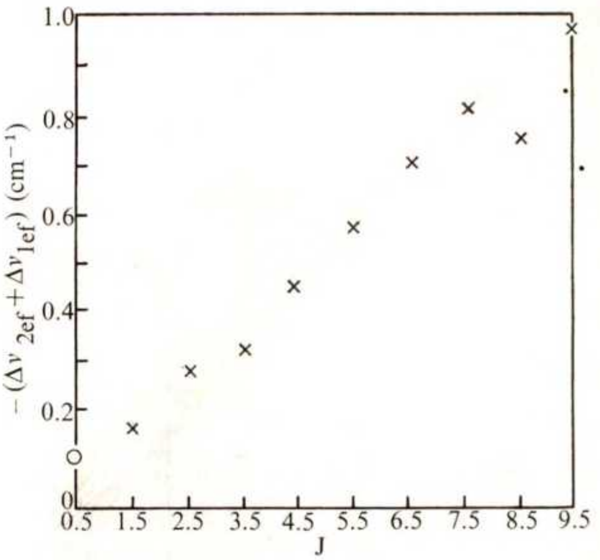

Fig. 1 Extrapolated experimental Λ-doublet splittings and the calculated value, experimental values of $-(\Delta\nu_{2ef}+\Delta\nu_{1ef})$ come from ref. 10, ×, experimental points; ○, theoretical calculation for $J=\frac{1}{2}$.

Calculations are more difficult for SiH than for the similar CH species, since less is known about the perturbing excited states, and extra complications are introduced by the presence of a second row atom[5]. Nonetheless, predictions can be made if the approximations introduced by Van Vleck[6] are used. To second order the splitting of energy levels of a $^2\Pi$ state may be expressed in terms of two parameters p and q, and the splitting in the lowest rotational level of a $^2\Pi_{\frac{1}{2}}$ state is given by $(\frac{1}{2}p+q)$, where:

$$p=4\sum\frac{\langle{}^2\Pi|H_{\mathrm{SO}}|{}^2\Sigma\rangle\langle{}^2\Sigma|B(L^{+}+L^{-})|{}^2\Pi\rangle}{E_{\Pi}-\mathrm{E}_{\Sigma}}$$

$$q=2\sum\frac{|\langle{}^2\Sigma|B(L^{+}+L^{-})|{}^2\Pi\rangle|^2}{E_{\Pi}-E_{\Sigma}}$$

The summations extend over all vibrational levels of all $^2\Sigma$ states, with contributions from $^2\Sigma^-$ states being taken as negative. Matrix elements are taken over both electronic and vibrational wave functions; H_{SO} is the spin-orbit coupling operator and B is the operator $h/8\pi\ \mu r^2$.

Table 1 Λ-type doubling in the X $^2\Pi_{\frac{1}{2}}$ ($v=0$, J $=\frac{1}{2}$) state of SiH

	p(cm^{-1})	q(cm^{-1})
Contribution from B $^2\Sigma^+$	0.02867	−0.00119
Contribution from $^2\Sigma^-$	0.05393	0.01273
Total contribution	0.08260	0.01154
Extrapolated experimental doubling	2,940 ±300 MHz	
Calculated doubling	3,168 MHz	

Attention is restricted to the influence of the B $^2\Sigma^+$ state and an unobserved $^2\Sigma^-$ state. Electronic wave functions for the X $^2\Pi$ state and the $^2\Sigma$ states were obtained using the ALCHEMY *ab initio* wave function computer program[7], including configuration interactions, using six configurations for the X $^2\Pi$ state, eight for the B $^2\Sigma^+$ state and five for the $^2\Sigma^-$ state.

Vibrational wave functions were obtained from the computed multiconfigurational potential curves for the X $^2\Pi$ and B $^2\Sigma^+$ states, but the $^2\Sigma^-$ state is found to be repulsive. For this latter state vibrational wave functions were obtained using the box normalisation technique of Gordan[8] and Czarny *et al.*[9] and the contributions to p and q have to be integrated over the energy of the state.

The various contributions to p and q and the predicted doubling of the lowest level of SiH $^2\Pi_{\frac{1}{2}}$ are given in Table 1. The figure shows the theoretical prediction compared with the experimental extrapolations. The agreement is close enough to provide some encouragement for a search for the molecule in interstellar space to be conducted, using available receivers.

Haze in the stratosphere

On September 1, 1975 I flew as a passenger on Concorde flight OF269 from Heathrow to Gander taking off shortly before 0730, arriving at Gander shortly before 1000 (London time). The return journey on flight OF277 started an hour later and arrived at Heathrow shortly before 1400. Over the Atlantic we climbed gradually from ~ 50,000 feet to ~ 56,000 feet.

I watched carefully for visual evidence of the tropopause throughout the flights. During the descent to Gander cirrus clouds extended up to 44,000 feet. There was occasionally slight clear air turbulence, sometimes regular enough to indicate a billow wavelength of ~ 120 m, at many different heights in the stratosphere, but most remarkable of all was the extent of haze layers.

The distant horizon was the cirrus cloud top which was variously at heights between 35,000 and 44,000 feet. Above that the sky had a whitish glow, and as we ascended, several discrete layers, in which the haze was denser, were revealed as we came to the top or bottom of the layer. When the sun was low, on the outward flight, they were brown coloured in the north-west; when the sun was high on the return flight at the eastern end, they glowed white in the south-east. I had a forward starboard window. The highest layers were still above the aircraft at 56,000 feet, and the sky glowed with a paler blue than on occasions when I have observed the colour of the stratosphere from jet aircraft, for example Comets, at ~ 35,000 feet. On this occasion the weather ship radiosondes indicated a very obvious tropopause at ~ 39,000 feet but it certainly did not stand out visually.

The haze extended all the way across the Atlantic, and its extent is very significant. We tend to think of haze as a cooling agent for the air, because that is what it is in normal low altitude pollution situations; but on this occasion it was a warming agent, being probably below the radiation equilibrium temperature between the Earth and outer space. Thus the presence of haze facilitates the ascent of air without adiabatic cooling in the stratosphere, and on this occasion could well have been associated with the exceptionally large descent taking place above hurricane Donna further south in the Atlantic.

The importance of this observation is that it makes nonsense of the assumption, implicit in almost all theories concerning the consequences of putting pollution into the stratosphere, that practically everything that can, in the usual rainmaking processes, be rained out as air ascends into the stratosphere, actually is rained out and thus removed. This includes NO_x, sulphur compounds, such as SO_3, and ammonium sulphate, and a large range of organic compounds of which the most important, in today's context of ozone depletion scares, is methyl chloride.

It is probably not necessary to look further than the normal natural interchange mechanisms across the tropopause for the greatest supply of all these substances to the stratosphere, and it is easy to stipulate that mother-of-pearl clouds are formed on layers of sulphate haze at heights around 80,000 feet. The implications of these observations make nonsense of the ozone depletion theories which depend absolutely on a degree of stratospheric purity that is quite unrealistic. Furthermore the ascent of such a vast extent of air on an occasion such as this makes nonsense of the supposition that the vertical transport mechanisms in the stratosphere can be correctly represented by diffusion mechanics in which all ascending chemical species mix and react chemically with all descending chemical species. Ozone depletion theories are based completely on diffusion models.

Continuous plankton records show fluctuations in larval fish abundance during 1948–72

The continuous plankton recorder (CPR) survey[1] has sampled the plankton at a depth of 10 m around the British Isles consistently since 1948. Analysis of this material has revealed a number of trends[2,3] in the distribution, abundance and timing of seasonal cycles of zooplankton and phytoplankton. This report discusses similar changes in the distribution and abundance of planktonic fish larvae.

Counts of fish larvae from selected recorder samples are allocated to statistical rectangles of 1° latitude by 2° longitude, and the mean number of fish larvae per recorder sample per month is calculated for each rectangle. These means are then used for the analysis of variability in distribution and abundance.

In the North Sea, at a depth of 10 m, there has been a decline in abundance of some larvae (for example *Odontogadus merlangus* (whiting), *Trisopterus esmarkii* (Norway pout), *Limanda limanda* (dab) and *Pleuronectes platessa* (plaice), and for some species (for example *O. merlangus*, *P. platessa and Ammodytes* spp. (sand eels)), a shortening of the season during which the larvae have been caught, and a delay in the time of the seasonal maximum abundance. Examples of these changes are given in Fig. 1, which shows monthly and annual fluctuations in the abundance of larvae of *O. merlangus* and *P. platessa* from recorder sampling in the North Sea. The larvae of both species declined in abundance over the period; the downward trend of *O. merlangus* started in 1964, whereas for *P. platessa* there has been a general trend over the whole 25-yr period. In both species the time when most larvae were sampled has shifted to later in the season and the season itself has shortened. These patterns bear a close resemblance to those found for the zooplankton and phytoplankton in the CPR survey; over the same period the total numbers of copepods and the zooplankton biomass in the North Sea have declined[2], the duration of the

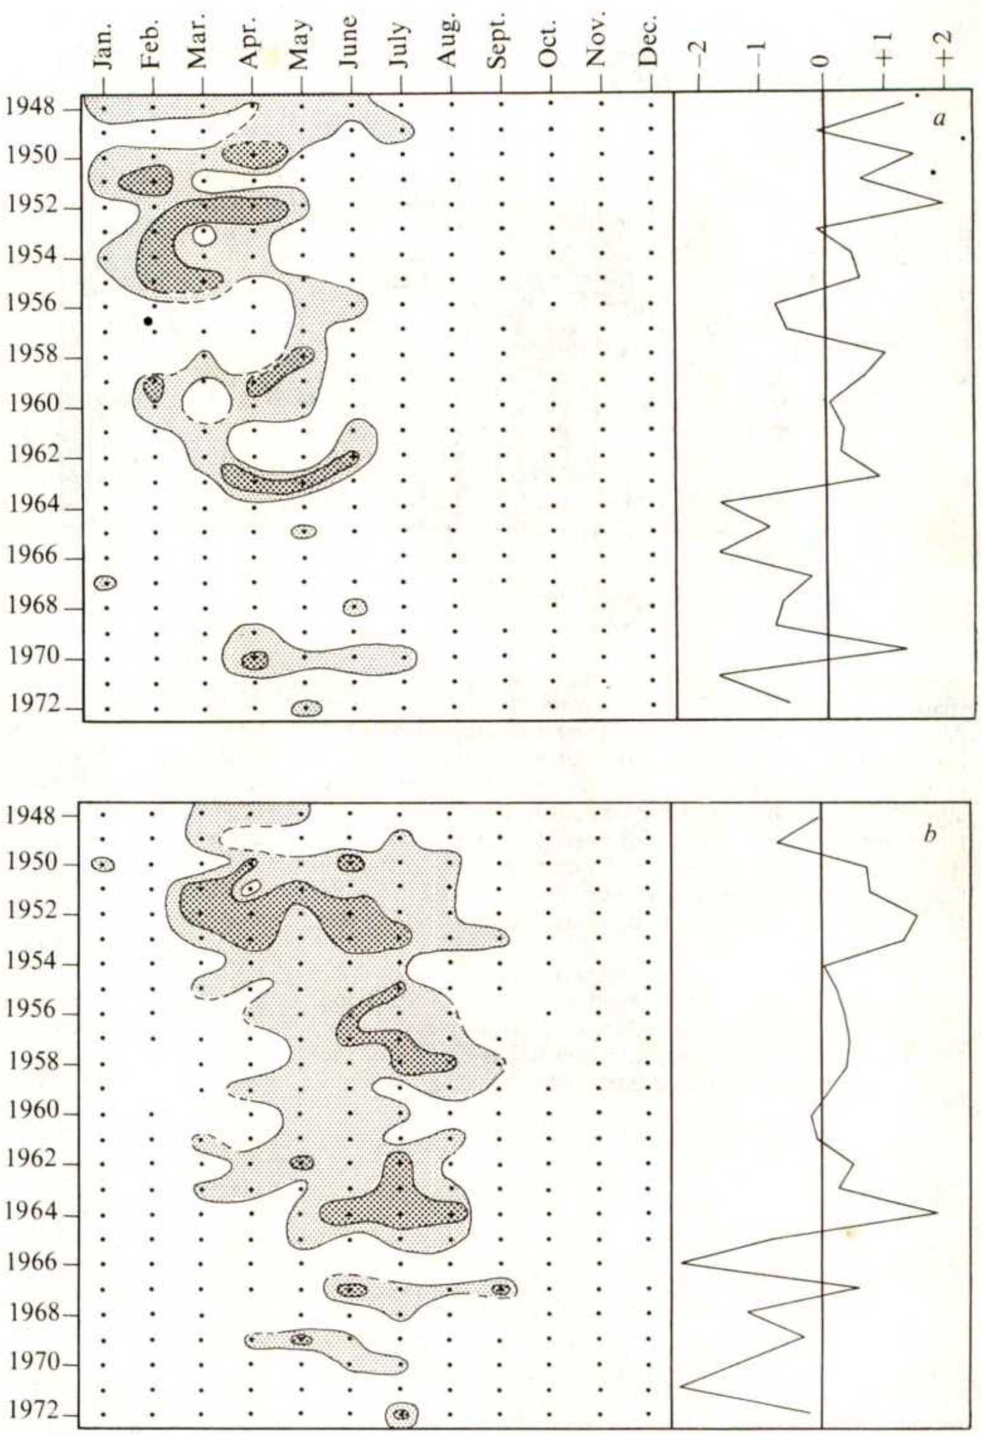

Fig. 1 Monthly fluctuations in abundance of: *a*, *Pleuronectes platessa* and *b*, *Odontogadus merlangus* from 1948 to 1972, obtained from CPR sampling in the North Sea. Contour levels as mean numbers of fish per recorder sample are 0 and 0.05 for both diagrams; missing dots represent months with inadequate sampling. The right hand section of each diagram shows the fluctuations in annual abundance, standardised about a zero mean and plotted as standard deviation units. Annual abundance indices were obtained by summing monthly means.

zooplankton season has become progressively shorter[2], and the spring bloom of phytoplankton has become progressively later[2].

Similar changes have been recognised in CPR sampling of young fish in the English Channel and north-eastern Atlantic; charts showing the distribution of a common mid-water fish, *Stomias boa ferox* (dragonfish), for two periods are illustrated in Fig. 2. From 1948 to 1967 larvae were found only over deep water beyond the continental shelf, whereas from 1968 to 1972, the northern limit of distribution was much further south, and larvae were found over the shelf extending into the English Channel. These larvae had not hatched recently, so that their occurrence in the Channel was probably the result of drift from their spawning areas near the continental slope. Such an incursion of larvae into the Channel, observed since 1968, supports the hypothesis of an increased easterly flow of water through the Channel since about 1965, as proposed by Russell *et al.*[4].

A southerly shift in the distribution of other fish larvae (like that of *Stomias* after 1967) is apparent from the CPR survey (for example *Melanogrammus aeglefinus* (haddock), *Micromesistius poutassou* (blue whiting)[5,6], *Scomber scombrus* (mackerel), and *Hippoglossoides platesssoides* (long rough dab)), and similar changes in the geographical distributions of fish[4,7] and other marine animals[4,8], have been reported indicating an increased boreal influence from about 1965.

The seasonal period during which most of the *Stomias* larvae are found in the Western Approaches has shifted from March and April (between 1948 and 1961) to April, May and June (from 1968 to 1972). Since about 1965 there have been indications of a coincident shift in the main season of abundance of pilchard eggs in the Channel to later in the year[4].

These changes in timing, abundance and distribution of fish larvae in the CPR survey add to the increasing evidence[4,7,12] that many, perhaps most, pelagic organisms underwent a marked

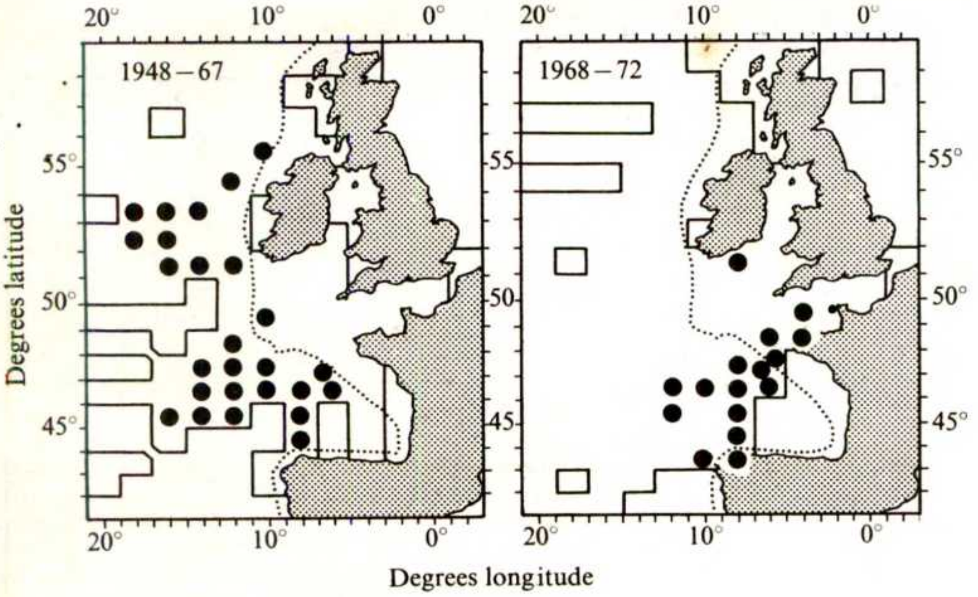

Fig. 2 The distribution of the larvae of *Stomias boa ferox*. Black dots indicate statistical rectangles in which larvae were found. The sampled area, from February to October, inclusive, is outlined, and the 200-m contour shown by a dotted line.

change in about 1965–67, in the waters of the north-western Atlantic and North Sea. Such a coherent and widespread pattern of change seems likely to have had its origin in climatic events[9,10]. It is conceivable that climatic change may have affected the distribution of the adult fish, here reflected in the larval distribution, but it is also possible that the changes in the fish larvae have been caused by corresponding changes in the primary and secondary trophic levels, arising from the dependence of survival of young fish on the availability of prey organisms[11].

I thank the captains and crews of vessels which towed recorders and Dr G. T. D. Henderson, the late V. Bainbridge and G. A. Cooper who analysed most of the samples for young fish. The research was supported by NERC as part of the programme of the Institute for Marine Environmental Research.

Structure of graphite by neutron diffraction

THE structure of graphite[1] consists of layers of linked hexagons of carbon atoms. The layers are stacked in a $\cdots$ ABAB $\cdots$ sequence so that half the atoms in a layer are directly above and below carbon atoms in the adjoining layers, and half are directly above and below centres of the hexagons. The hexagonal unit cell contains atoms at the (0, 0, 1/4), (1/3, 2/3, 1/4), (0, 0,–1/4) and (2/3, 1/3,–1/4) positions. Modifications to this structure have been proposed by several workers. Lukesh[2] reported diffraction patterns indicating a lower symmetry, and Pauling[3] has proposed an orthorhombic structure in which the interconnected six-membered rings are distorted so that two-thirds of the bonds are longer. Pauling based his model on the high compressibility of the basal planes, and considerations of stacking bonds in the layered structure. Ergun[4] suggested that data on pyrolitic graphite indicated an apparent quinoid structure in the graphite layers, but errors in his analysis have been reported[5]. X-ray and neutron diffraction studies of graphite were undertaken in our laboratory to study the details of the electron charge density and atomic motion in the graphite structure. The results of the neutron diffraction work show that all in plane carbon–carbon distances have the same value 1.422 ± 0.001 Å.

X-ray diffraction photographs of almost seventy small, natural single crystals of graphite indicated that two or three were of exceptional quality. The largest was a six-sided plate 0.2 mm thick, approximately 2 mm long and 1.4 mm across. This crystal was glued to a glass fibre, so that the axis of the fibre was parallel to the basal planes of the sample. Measurements were made on the full-circle automatic diffractometer at station H6S3 of the Brookhaven HFBR. A Ge (220) reflection was used to make the beam monochromatic, with wavelength of 1.02041 Å. Vertical in-pile soller slits and horizontal soller slits between the monochromator and sample were used. A $\frac{1}{2}'' \times \frac{1}{2}''$ receiving slit, 16″ from the sample and in front of the detector, was used. Twenty-seven reflections equally distributed over the diffracting sphere were centred to obtain accurate cell dimensions. A least-squares refinement of the angular positions of these reflections resulted in the unit cell dimensions and angles shown in Table 1. Assuming a triclinic cell, the a and b axes were equal to within σ (estimated standard deviation) and the angles between the unit cell vectors were 90°, 90°, and 120°, within 1–2σ. Refinement assuming a hexagonal cell led to the lattice parameters also shown in Table 1.

Intensity data were obtained for 339 reflections, including all symmetry-related reflections within the 0.75-Å diffracting sphere. Step scans through each reflection were made in the

R		4.6%	4.6%	4.9%	4.2%

θ–2θ mode with a scan width of 2θ of 4.5°–6.0° and a step width of 0.06°. Of the 339 reflections measured, 52 would have zero intensity if the classical structure is correct. Of these 52 intensities, 38 were less than σ, 48 were less than 2σ and four could not be reduced because of uneven backgrounds or fluctuations. The standard deviations were based on counting stastistics. No attempt was made to measure these reflections to a high degree of accuracy, and they were not used in the succeeding refinements. Examination of the intensity data indicated extinction effects were small and these corrections were neglected.

Thermal parameters of the form $\exp(-\beta_{11}h^2-\beta_{22}k^2-\beta_{33}l^2-2hk\beta_{12}-2hl\beta_{13}-2kl\beta_{23})$ were used for C_1 and C_2. Initial refinements resulted in values of β_{11}, β_{22}, β_{12}, β_{13} and β_{23} that were smaller than estimated standard deviations for these parameters. Refinements setting these parameters equal to zero, and equal to values derived from other measurements of the mean square amplitude of vibration in the basal plane were carried out. No significant effects on the positional parameters were observed. The results of the refinements (Table 2) were obtained by assuming mean square amplitude of vibration of 0.0031 Å^2 in the basal plane, based on neutron measurements by Ludsteck[6].

Four full-matrix least-square refinements were done with varying restrictions on the structural parameters. In the first, a centre of symmetry was taken at the origin and no restriction was put on the positions of the two independent atoms in the unit cell, C_1 and C_2. The results of this refinement in space group $P\bar{1}$ indicated that the atoms in the basal planes are planar to within ±0.001 Å, and the classical structure of graphite is consistent to within 2σ. In the second refinement, it was assumed that the basal planes were truly planar, enabling one to fix the position of C_1 and refine only the x, y coordinates of C_2. The results of this refinement were not significantly different from the first. Ergun's proposed structure[4] restricted the position of atom C_2 so that the x, y coordinates were related by $y = 1-x$. The intensity data were averaged to a quarter sphere assuming

$$I(hkl) = I(\bar{h}\bar{k}\bar{l}) = I(hk\bar{l}) = I(\bar{h}\bar{k}l).$$

This refinement in space group $P2_1/m$ provided further confirmation of the classical structure of graphite. If the Bernal structure[1] is assumed, only the thermal parameters are variables in the refinement. This refinement was done averaging the data to 1/24 of the sphere. Results of all four refinements are shown in Table 2.

The thermal parameters for C_1 and C_2 are not significantly different. The mean square amplitude of vibration perpendicular to the basal plane for C_2, which has voids above and below it, is nominally higher than that of C_1. These mean square amplitudes of vibration correspond to Debye temperatures of 490±40 K and 470±40 K for C_1 and C_2 respectively. These compare with Ludsteck's determination of the average graphite Debye temperature for out-of-plane vibrations of 670^{+100}_{-70} K (ref 6).

No indication of the proposed modifications of the graphite structure can be found in our data. Pauling predicted that two-thirds of the carbon–carbon bond distances may be 1.448 Å and one third 1.366 Å. Comparable figures for the Ergun modification are 1.455 Å and 1.355 Å. Our results show that all in-plane carbon–carbon bond distances are 1.422±0.001 Å. It should be pointed out that this distance is averaged over time and over a large number of unit cells by the diffraction process.

The authors wish to acknowledge the assistance of Dr Graheme Williams and the Chemistry Department of Brookhaven National Laboratory. This research was supported by a grant from the NSF.

Photo-orientation of anisotropically absorbing molecules

THE action of plane-polarised light on anisotropically absorbing molecules produces an induced anisotropy in an ensemble of molecules, which can be detected by double refringence, dichroism and other optical phenomena. The phenomenon was first observed[1] on dye molecules in liquid[2], although its nature and mechanism by which it operates remain unexplained—neither can they be explained by the optical Kerr effect[2].

Analysis of existing experimental material[1,2] shows that there is a new kind of nonlinear optical phenomenon which takes place only upon the interaction of plane-polarised light with anisotropically absorbing molecules and which is resonant. Therefore, it can be observed at weak intensities using non-laser sources.

We suggest a classical model for an assembly of damped linear oscillators at resonance in a plane-polarised electric harmonic field. Each oscillator behaves according to the equation

$$m\ddot{x}+2mr\dot{x}+mf^2x = eE\cos\theta\cos ft \qquad (1)$$

where m and e are the electron mass and charge, respectively, r is the damping coefficient, E is the amplitude of the electric field in an incident light beam, θ is the angle between the direction of the applied force and the axis of the oscillator, and f is the resonance frequency. The total energy of the oscillator is:

$$W(\theta) = (eE\cos\theta)^2/8mr^2 \qquad (2)$$

The dependence on the angle θ leads to the appearance of a moment of force, $-(\mathrm{d}W/\mathrm{d}\theta)$, which tends to orient the oscillator perpendicularly to the direction of the electric field in a light beam. The anisotropy of the ensemble of mutually non-interacting oscillators at a given temperature, T, is subjected to the Boltzmann distribution

$$P(\theta) = C\exp(-W(\theta)/kT) = C\exp(-b\cos^2\theta) \qquad (3)$$

where $b = (eE)^2/8mr^2kT$. Under plane-polarised resonance illumination the angular distribution of the oscillators becomes non-random. This photo-induced anisotropy causes several nonlinear optical effects: deviation from Beer–Lambert law for plane-polarised light, photodichroism, and dependence on incident light intensity of the double refringence. Using the angular distribution function (3) these effects can be calculated with standard methods of statistical physics[3].

The magnitude of the photo-orientation of anisotropically absorbing dye molecules can be evaluated at a weak field strength, 3 V cm^{-1}, which corresponds to the incident light intensities given in ref. 2. The damping coefficient, r, can be evaluated from the lifetime of the electronic excitation: $r = 1/\tau$. For dye molecules in a liquid, $\tau \sim 10^{-8} \div 10^{-9}$ s (ref. 2). At room temperatures, when $\tau \sim 10^{-9}$ s the nonlinearity coefficient b is $\sim 10^{-1}$. The corresponding value for the optical Kerr effect in such a weak field is $b_K = \alpha E^2/2kT \sim 10^{-13}$ (ref. 3). At resonance, the polarisability is $\alpha = e^2/4mfr$. Also, $b_K/b = r/f \sim 10^{-6}$. This explains the fact that photo-orientation induced by absorption was observed before the discovery of the laser and before the observation of the optical Kerr effect. The value of the nonlinearity coefficient being known, the photodichroism can be calculated using standard methods[2,3]

$$d = (D_{\parallel} - D_{\perp})/D = -0.5[\langle\cos^2\theta\rangle - 0.5\langle sin^2\theta\rangle] \approx b/15 \qquad (4)$$

where D, $D_{\parallel}$, $D_{\perp}$ are, respectively, the optical densities of natural light, and light polarised parallel and perpendicular to the polarisation plane of the orienting light beam. If $b \sim 10^{-1}$, then $d \sim 10^{-2}$, which is of the same order as the experimental value of photodichroism observed by Neporent and Stolbova[2].

The electronic structure of VO^{2+}, CrO^{3+}, and MoO^{3+} complexes

THE electronic structures of the d^1 chromophores VO^{2+}, CrO^{3+}, and MoO^{3+} have been the subject of much debate[1–4], particularly after the early molecular orbital (m.o.) calculations of Gray *et al.*[5,6]. An important feature of the electronic spectral assignments suggested[5,6] was that the first two absorptions correspond to the d–d transitions $d_{xy} \rightarrow d_{xz,yz}$ and $d_{xy} \rightarrow d_{x^2-y^2}$, respectively, in the d-orbital sequence d_{xy} (b_2) < d_{xz}, d_{yz} (e) < $d_{x^2-y^2}$ (b_1) < d_{z^2}(a_1). These assignments have found general acceptance and have formed the basis for the interpretation[7] of the electron spin resonance (ESR) spectra and bonding parameters of these complexes. We report here experimental results contradicting the assignment of the second absorption.

We have obtained, for the first time, polarised single crystal electronic spectral data for CrO^{3+} and MoO^{3+} complexes of known structure, including $[(C_6H_5)_4As][CrOCl_4]$, $[MoOCl_3(OP(N(CH_3)_2)_3)_2]$, and $[(C_6H_5)_4As][MoOCl_4(H_2O)]$, at room, liquid nitrogen and liquid helium temperatures. These data, together with certain features apparent[3,4,8] for VO^{2+} complexes, show that several similarities exist between the electronic spectra of VO^{2+}, CrO^{3+}, and MoO^{3+} species (with the possible exception of fluoro- complexes).

(1) The energies of the first two absorptions are characteristic of the MO moiety and are essentially independent of the nature of the other ligands present. VO^{2+} complexes exhibit these absorptions at ~ 13 and 17 kK and MoO^{3+} complexes at ~ 13 and 22 kK. There are few spectral data available at present for CrO^{3+} complexes, but it is tentatively suggested that common absorptions occur at ~ 13 and 18 kK. These observations suggest that the second lowest energy absorption cannot be due to the $d_{xy} \rightarrow d_{x^2-y^2}$ transition as this should be very sensitive to the nature of the ligands *cis* to the M–O group.

(2) These two lowest energy absorptions are polarised. Both are allowed when the electric vector of the incident light is perpendicular to the M–O axis, and forbidden when it is parallel to this direction. Since C_{4v} symmetry is either exact or at least a close approximation for the actual structure of these chromophores, it follows that these two lowest energy electronic transitions must be $E \longleftrightarrow A(B)$ in character. $d_{xy} \rightarrow d_{x^2-y^2}$ is a $^2B_2 \rightarrow {}^2B_1$ transition and is forbidden in both polarisations of C_{4v} symmetry.

(3) The sense of the polarisation and the absolute intensity of the first two absorptions remains essentially unchanged on cooling from room to liquid nitrogen and/or liquid helium temperatures. We therefore conclude that both transitions are electronically allowed. Although $d_{xy} \rightarrow d_{x^2-y^2}$ is symmetry forbidden, it could possibly give rise to an absorption of the observed polarisation by coupling with an E vibrational mode. If this were the case, however, a marked reduction in the intensity and the extent of the polarisation should be observed on cooling.

(4) Fine structure becomes apparent for these first two absorptions on cooling. In each case, the most common spacing of these details are ~ 900 cm^{-1} for the first absorption and ~ 300 cm^{-1} for the second.

To aid the interpretation of the electronic structure of these complexes we have performed *ab initio* m.o. calculations for the ground and excited states of certain CrO^{3+} and VO^{2+} complexes. These results indicate that the lowest energy absorption corresponds to the $^2B_2 \rightarrow {}^2E$ transition, $d_{xy} \rightarrow d_{xz,yz}$, or more correctly $M(d_{xy}) \rightarrow M\text{–}O(\pi^*)$. This interpretation is in agreement with the conclusions of Gray *et al.*[5,6] and all the above experimental data. The fine structure associated with the transition is assigned to vibronic coupling with the M–O stretching mode of the first electronic excited state. In every instance the M–O stretching frequency seems to be less in the excited than in the ground state, as expected in view of the nature of the transition.

The experimental and theoretical evidence available at present for VO^{2+}, CrO^{3+}, and MoO^{3+} complexes gives definite guidance concerning the nature of the second lowest energy absorption, but does not allow for an unequivocal assignment. Self-consistent field calculations[2] for $[CrOF_5]^{2-}$ suggest that this absorption corresponds to a $^2B_2 \rightarrow {}^2E$ electronic rearrangement which is predominantly $M\text{–}O(\pi) \rightarrow M(d_{xy})$ in character, whereas configuration interaction calculations for $[CrOCl_4]^-$ suggest that the transition primarily involves the $^2B_2 \rightarrow {}^2E$ promotion, $M\text{–}O\,(\pi) \rightarrow M\text{–}O(\sigma^*)$, where the latter is the metal–ligand antibonding orbital involving d_{z^2}. Both of these assignments are consistent with points (1)–(4). The origin of the fine structure being attributed[9] to vibronic coupling with the ML_{cis}

B_1 stretching mode, this coupling being necessary[9] to remove the excited state orbital degeneracy. Both suggested electronic transitions have excited state spatial degeneracy within orbitals localised essentially on the oxygen atom, where—in contrast to the first electronic transition where the excited state orbital degeneracy is concentrated on the metal centre—spin–orbit coupling effects are unlikely to remove adequately the spatial degeneracy. Since the calculated ^2E excited state wave functions for the second lowest energy transition are an admixture of several electronic promotions, including the two cited above, it may not prove possible to give a simple description for the origin of this absorption.

The evidence we now have about the electronic structure of VO^{2+}, CrO^{3+}, and MoO^{3+} complexes clearly indicates a considerable similarity in their electronic structure. As generally assumed, the lowest energy absorption is essentially metal $d_{xy} \rightarrow d_{xz,yz}$ in character but the next absorption cannot be due to the $d_{xy} \rightarrow d_{x^2-y^2}$ transition to which it is usually attributed. This latter absorption seems to be due to an oxygen–metal charge-transfer rearrangement within the M–O group. This alternative interpretation destroys the basis used[7] for the interpretation of the ESR spectra of these complxes and thus negates conclusions concerning the nature of bonding parameters so derived.

We thank the SRC for financial support.

Singular behaviour of small crystallites near the melting point

DURING an extension of some recent *in situ* electron microscope investigations into the melting of small particles[1,2], some unexpected effects at temperatures near the melting point were observed for micron-sized crystallites of lead and bismuth. In particular, an unusually enhanced form of diffusion (termed 'snapping') occurred in which many crystallites changed their shapes abruptly into more compact solid forms. Experiments on somewhat smaller crystallites of tin have shown a similar behaviour. Changes of shape during the continuous deposition of thin films in an electron microscope have been reported by other workers[3,4]; these, however, were of a more gradual character, and were consistent with normal diffusion processes.

A second phenomenon observed was the apparent bodily displacement (or 'crawling') of lead crystallites by distances comparable with their length. Small movements of the centre of mass of crystallites due to a change of shape have been noted by other workers[5] and have also been observed in the present work, but these do not involve the

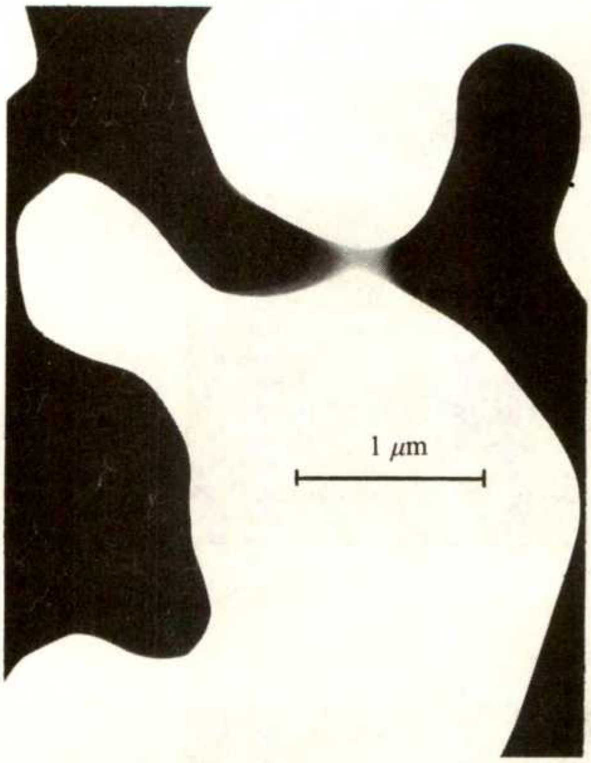

Fig. 1 The rupture, by atomic diffusion, of a neck formed in a thin film of lead (1-s exposure time). Although this diffusion is faster than usual, due to the high curvatures involved, the change is sufficiently slow to cause the edges to be blurred.

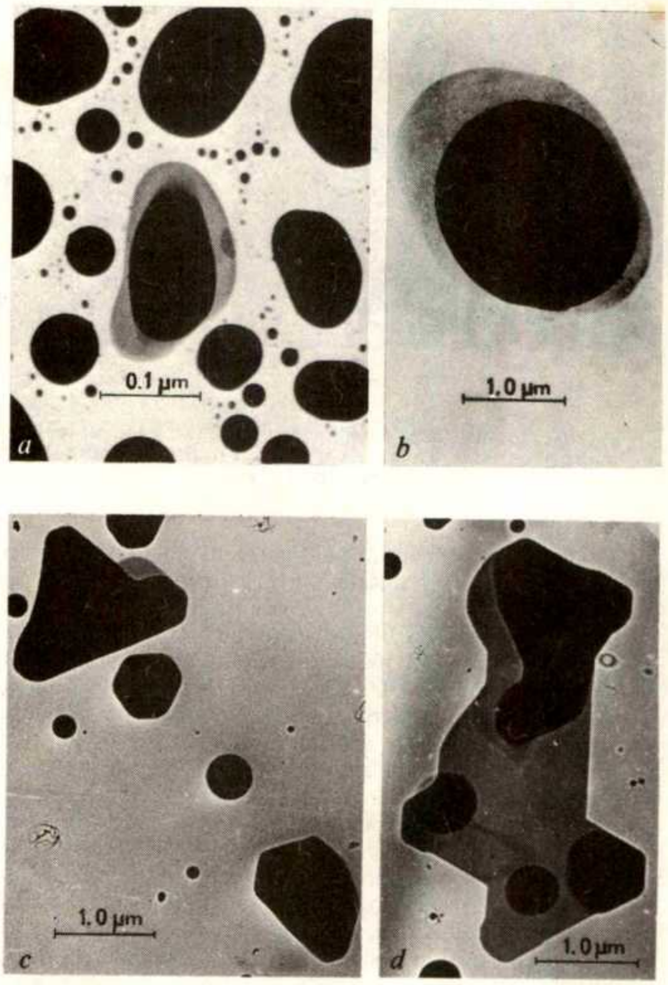

Fig. 2 Snapping in small crystallites (1-s exposure time). *a*, A tin crystallite; *b*, a lead crystallite, showing snapping and subsequent melting; *c*, bismuth particles; *d*, a bismuth crystallite snapping in to two solid and two liquid particles.

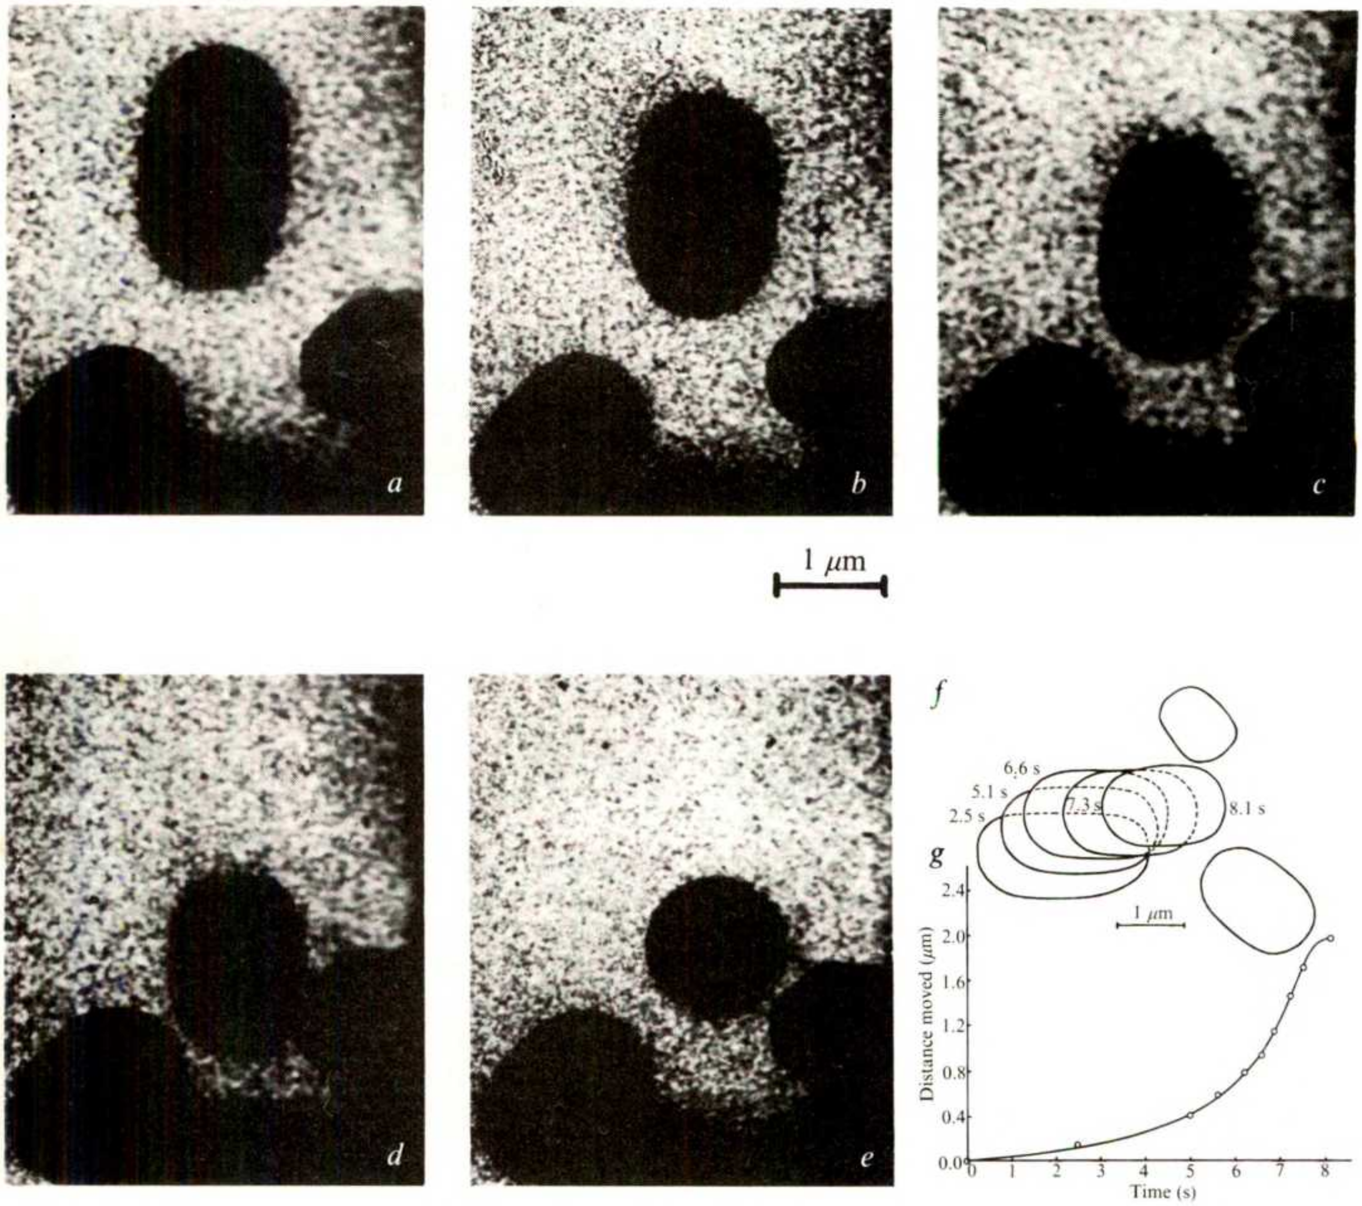

Fig. 3 *a–e*, Frames taken from a cine film showing the movement (and in the final frame the melting) of a lead crystallite relative to some stationary particles. The time with respect to the start of the moment in each case is: *a*, 5.1 s; *b*, 6.6 s; *c*, 7.3 s; *d*, 8.1 s; *e*, 15.6 s. *f*, Scale diagram showing the movement of the crystallite in Fig. 3*a–e*. *g*, Distance of movement plotted against time for the crystallite in Fig. 3*a–e*.

simultaneous movement of all parts of the crystal in a given direction. It is this fact which defines 'crawling' in the present work.

The experiments on bismuth and tin were performed in a JEM 6A electron microscope at a residual gas pressure of about 7×10^{-5} Pa (5×10^{-7} torr), and those on lead in a JEM 100U electron microscope at a residual gas pressure of about 10^{-5} Pa. The specimen films were evaporated *in situ*, usually on to amorphous carbon substrates of graphite, silicon monoxide and partially oxidised aluminium films. After deposition, the specimens were heated at rates ranging from 1 K min^{-1} to 10 K min^{-1}. In general the phenomena described were more pronounced at the faster heating rates. Records were made using either the normal internal plate camera, or a cine camera focused on the screen from a position outside the microscope.

Initially, the lead and bismuth deposits consisted of almost continuous films, containing narrow channels, while the tin deposits comprised individual irregular platelets. On heating, the first noticeable effect was the movement of grain boundaries, resulting in an increase in the size of the grains. In the case of tin, this caused many of the particles to become single crystals, although they retained their irregular shapes. For the bismuth and the lead films, the channels increased in width because of atomic diffusion until the films formed first a network and then (usually within 40 K of the bulk melting point) individual, irregular platelets. This diffusion was slow except in regions of high (convex) curvature, particularly at points where, by the thinning of the material connecting two large particles, 'necks' formed and subsequently ruptured (Fig. 1). The resultant 'needle points' rounded off very rapidly at first, and then more slowly as shapes of lower curvature were formed. As expected, the rate of diffusion was observed to increase with temperature. Little diffusion of this type occurred in the specimens of tin which were already in the form of individual crystallites.

When the films were heated to within a few degrees of the melting point, very abrupt changes of crystal shape were observed to occur for all three materials; this effect was independent of the base used. This was first noticed as the appearance of double images on micrographs taken during the experiments (Fig. 2). During the period of the exposure of the photographic plates (~ 1 s), some crystallites suddenly snapped from a thin form (the larger outlines in Fig. 2) to a more compact form. In other experiments, cine camera records showed no intermediate stage in this process, thus demonstrating the very rapid nature of the change—for example, in the case of bismuth, the change was completed in less than 0.04 s. This behaviour was not necessarily associated with particle forms differing markedly from equilibrium (as, for example, in the necking shown in Fig. 1).

The effect differed slightly for each of the three materials used. For tin (Fig. 2*a*) the change of shape was often symmetric; material from all the side faces building on to the top (and perhaps the bottom) surface. Occasionally, tin particles exhibited a double snapping in which two such abrupt changes occurred one after another, separated in time by ~ 1 s. For lead, the movement was also generally symmetric, but was often followed within a few seconds by melting (Fig. 2*b*). For bismuth the change was, as a rule, asymmetric with the product located towards one side of the initial crystallite. Usually one or more of the original side faces were preserved (Fig. 2*c*) and frequently the snapping resulted in the formation of two or more separated parts, some of which were often liquid droplets (Fig. 2*d*).

When heated to a temperature close to the bulk melting point, several of the lead crystallites were observed to crawl steadily on amorphous carbon substrates; during these movements there were gradual reductions in the projected areas of the particles, which became more compact. Figure 3*a–c* shows a sequence of photographs illustrating the crawling process, and Fig. 3*f* is an outline diagram showing part of the movement, in detail, of the crystallite relative to the surrounding stationary particles. The distance travelled by the centre of gravity of the particle shown in Fig. 3*a–e* has been plotted as a function of time in Fig. 3*g*. The movement of each crystallite generally lasted several seconds, and resulted in a total displacement roughly equal to the length of the particle. The crawling was observed at both high and low electron beam intensities, but was not seen in experiments performed on substrates of silicon monoxide, graphite and partially oxidised aluminium. Crawling was also absent on amorphous carbon in preliminary experiments carried out in a vacuum of about 7×10^{-5} Pa. The liquid droplets obtained after heating to above the bulk melting point showed no sign of such movements.

These experiments are being continued and will be reported in detail in due course.

The experiments on bismuth were carried out by S.J.P. during the tenure of a Science Research Council maintenance grant, and those on tin by M.S.R. during his stay as a British Commonwealth Universities Scholar.

Aerodynamic properties of an insect wing section and a smooth aerofoil compared

IN this communication I report measurements of lift and drag forces acting on corrugated aerofoils. The chordal profile of the wings in many orders of insects is corrugated[1] and I have used scale models of a wing section of this type found in the hover fly *Syrphus balteatus* (Diptera, Syrphidae). The experimental profile is shown in Fig. 1*d*. The life-size chord length is 2.9 mm, and occurs 3.7 mm distal to the wing-root hinge, in a total unilateral wing length of 11.5 mm. (There is no special reason either for selecting this particular section or for choosing *S. balteatus*.) The model profiles were 22 times life size (chord length = 6.4 cm) and were made of stainless steel 100 μm thick. They were built to uniform chordal profile, with spans of 7.17 cm or 3.39 cm, giving aspect ratios of 1.12 and 0.53, respectively—both very low. An attempt was made to model the thick leading edge vein of the real wing by constructing the model leading edge from a stainless steel rod (diameter 1.7 mm).

Spanwise corrugation confers a large increase in spanwise stiffness (and allows a decrease in maximum membrane stress when the wing is subject to bending) by comparison with a flat plate of equal plane dimensions and mass. Because of the possibility that corrugations may be seriously detrimental to the aerodynamic qualities of a wing, the aerodynamic properties of the corrugated model were compared with those of another model of the same aspect ratio, of which the chordwise profile was that formed by drawing a smoothed 'envelope' through the corner points of the corrugated section. This is also shown in Fig. 1*d*, and was made of Perspex by grinding and polishing from a larger block.

The lift and drag properties of these models were tested in a small closed-circuit fluid flow channel filled with 45% aqueous

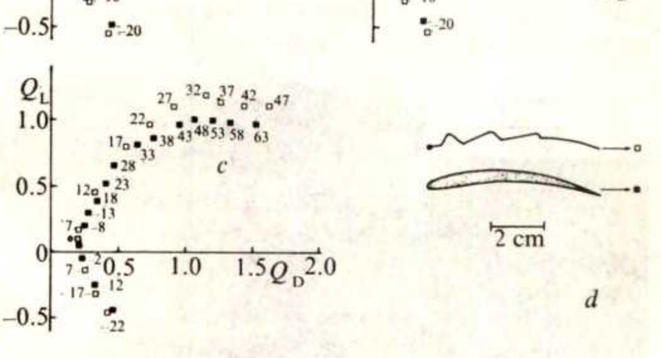

Fig. 1 *a–c*, Polar plots of quasi-lift coefficient Q_L against quasi-drag coefficient Q_D for the corrugated aerofoil (□) and its envelope (■). These profiles are shown in *d*. Small figures by each point refer to the angle of incidence at which that measurement was made. The use of the coefficients Q_L and Q_D and the experimental conditions in which they were measured are explained in the text. *a*, Reynolds number 900, aspect ratio 1.12; *b*, Reynolds number 450, aspect ratio 1.12; *c*, Reynolds number 800, aspect ratio 0.53; *d*, sections of corrugated aerofoil (stainless steel, 100 μm thick, with 2-mm leading edge wire, □) and its solid envelope (Perspex, ■). The corrugated chord section was modelled from a wing profile of the hoverfly *Syrphus balteatus* 3.7 mm distal to the wing root. (See ref. 1.)

sucrose solution. The external plan dimensions of the rectangular circuit were 120 cm × 70 cm, and the channel itself was 12 cm wide and was filled to a depth of 14 cm with the solution. The fluid was propelled round the channel by a 16-blade paddlewheel (diameter 60 cm) running in the long side of the channel opposite that containing the working section. This wheel was powered by a variable speed 500-W electric engine through a reduction gear and pulley system, so that free stream velocities in the range 4 to 25 cm s^{-1} were available. Curved parallel plates were fitted in the channel at its circuit corners, and there were honeycombs just upstream of the working section, which was itself about 8 cm × 11 cm in size. Over this section, the worst photographically measured velocity variations (using very small bubble markers) were -0.4 and $+0.2$ cm s^{-1} at a mean velocity of 8.4 cm s^{-1}, and -0.2 and $+0.3$ cm s^{-1} at 19.8 cm s^{-1}. The temperature of the fluid was maintained at 20 °C, so that the kinematic viscosity of the fluid, υ, was 7.79×10^{-6} $m^2 s^{-1}$ (7.79 cstoke).

The wing sections were mounted on a force balance in which the transducers were two orthogonally bonded pairs of silicon strain gauges (Pye 2A3A120P). When one set of gauges was loaded in its direction of maximum deformation, the other pair recorded a small error signal. The extent of this non-independence was about $+1.8\%$ ("lift" as affecting "drag" sensors) and $+0.95\%$ ("drag" as affecting "lift" sensors), and the results were corrected for this. The wing models were immersed in the flowing fluid such that lift would act perpendicular to the stream in a direction parallel to the channel floor, and drag would act parallel with the stream and the channel floor.

Force measurements were carried out at Reynolds numbers of 900, 800 and 450. These were considered to be values approximately appropriate to the wing of this fly, estimated from relationships given by Weis Fogh[2], and the wing-beat frequency and stroke angle data of Sotavalta[3]. In free flow around an aerofoil, undisturbed by the presence of walls and fluid surfaces, the lift and drag coefficients C_L and C_D may be determined from the expressions:

$$C_L = 2L/\rho u^2 A$$

$$C_D = 2D/\rho u^2 A$$

where ρ is the fluid density, *u* is its free stream velocity, *A* is the projected surface area of one side of the aerofoil perpendicular to chord and span, and *L* and *D* are the forces of lift and drag acting on the wing. In as small a channel as that used here, it is inevitable that there will be interference from the walls and fluid surface, and so the calculated force coefficients should not be interpreted as absolute values. I shall therefore symbolise these quasi-coefficients as Q_L and Q_D, and would stress that they apply to the flow system as described above, and are chiefly of interest from a comparative standpoint.

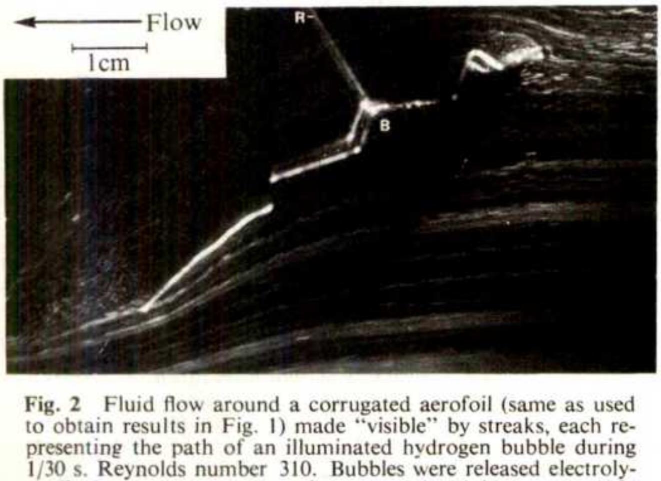

Fig. 2 Fluid flow around a corrugated aerofoil (same as used to obtain results in Fig. 1) made "visible" by streaks, each representing the path of an illuminated hydrogen bubble during 1/30 s. Reynolds number 310. Bubbles were released electrolytically from wire upstream of the aerofoil. Fluid, sucrose 45% (w/v) +0.04% NaCl; kinematic viscosity, 7.79×10^{-6} $m^2 s^{-1}$; aspect ratio, 0.53. R, Supporting wire (diameter 2 mm). B, Region where nearly stagnant fluid is trapped in fold. Incidence angle, 32°.

Conventional polar plots of Q_L against Q_D are shown in Fig. 1. The characteristics of corrugated and smooth envelope aerofoils are similar, especially in the comparisons with the models of higher aspect ratio. No abrupt stall is apparent from the plots at any of the Reynolds numbers, in fair agreement with Vogel's findings[4] for *Drosophila* wings, although the values of Q_L are in general higher than his measurements of C_L. Breakaway was, however, observed at lower angles of attack in regions of the aerofoil away from the tips than near the tips themselves. Figure 2 shows fluid flow around the corrugated section, which has been made visible by means of hydrogen bubbles electrolytically released into the fluid, using a method similar to that of Schraub *et al.*[5]. When the flow near the tip was examined in this way, it appeared that high velocity fluid passing round the wing-tip vortex was preventing the stagnation of fluid in the boundary layer on the upper surface of the wing, and thus eliminating the tendency to stall, up to high (35°) angles of attack; this is seen in Fig. 2 for an angle of incidence of 32°. Breakaway was, however, simultaneously well established at lower angles of attack (about 25°) in regions near the centre of the span of the corrugated or envelope wing with the larger aspect ratio. Instability in flight due to stall will be felt most severely when it occurs at the wing tip. Perhaps the chance of a wing-tip stall is reduced by this form of injection of high velocity fluid, derived from the wing tip vortex. Flow over a corrugated wing seems to involve some fluid becoming trapped in the folds (B in Fig. 2), where it is either stagnant, or rotates slowly about an axis parallel to the span of the wing. The main flow seems to behave as if these folds were solidly infilled and as if the aerofoil were more like the 'envelope' profile.

It thus seems that this wing profile has, at Reynolds numbers of a few hundred, all the advantages of low mass, high stiffness and low membrane stresses in bending which are associated with corrugation, without any obvious aerodynamic shortcoming by comparison with the smooth profile. Perhaps this conclusion may apply also to other corrugated wings which work at Reynolds numbers sufficiently low for the corrugation to present no "roughness" problem.

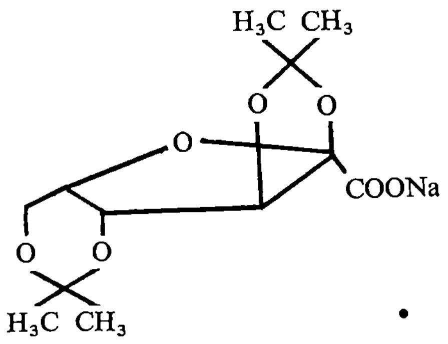
Group of new chemicals with plant growth regulatory activity

THE synthesis of L-ascorbic acid developed by Reichstein and Grüssner[1] is one of very few examples of large scale production of a biologically active monosaccharide. Although the importance of monosaccharides to plants has long been recognised, and several plant growth regulators have been discovered, few of these are carbohydrates and none is a monosaccharide. Active compounds which may be regarded as derivatives of monosaccharides, such as aminoglycosides[2], are chemically too complex to be synthesised on a large scale. We were therefore surprised to find that sodium 2,3:4,6-di-O-isopropylidene-α-L-xylo-2-hexulofuranosonate (I, accepted common name, dikegulac-sodium), an intermediate in the commercial synthesis of L-ascorbic acid, acts as a plant growth regulator.



(I)

To demonstrate the activity of this series of monosaccharide derivatives, Table 1 shows the growth-retarding activity of 11 compounds on *Poa pratensis* L. cv. Norma in the greenhouse. Water-soluble compounds were dissolved in water, and the others were formulated as wettable powders. A spray volume of 1,000 l ha^{-1} and concentrations of 6,000 and 3,000 p.p.m. were used.

The salts were generally more active than the esters although the pentyl and methyl esters were also highly active. As the sodium salt was the most active of the 11 compounds studied, its activity was tested in the greenhouse on a further 10 species (Table 2). Heights of *Lolium perenne* L. cv. Verna, *Digitaria sanquinalis* Scop., *Hordeum vulgare* L. cv. Union, *Malus sylvestris* Mill., *Vitis vinifera* L. Riesling. × Sylvaner and *Liqustrum vulgare* L. were recorded 4 weeks after treatment. The effect of dikegulac-sodium on petiole abscission was tested on *Phaseolus vulgaris* L. cv. Saxa. The plants were cut 1 cm from the main stem and lanolin paste containing the compound was applied to the cut ends. Abscised petioles were counted 6 d later. The effect on fruit ripening was tested on *Lycopersicum esculentum* Mill. cv. Rheinlandsruhm. The plants were sprayed when the first fruits turned red and ripe ones were counted 3 weeks later. Flowers on the first truss of *L. esculentum* Mill. cv. Tiny Tim plants were treated with the test solution using Luckwill's method[3]. Four weeks after treatment the fruits were cut and checked for seed production.

Table 1 Growth retardation activity of dikegulac-sodium and analogues on Kentucky blue grass (*Poa pratensis* L.)

Length 4 weeks after treatment (mm)	p.p.m. 6,000	p.p.m. 3,000
Untreated	197	
-sodium salt	40	40
-ammonium salt	42	52
-calcium salt	48	53
-morpholinium salt	45	45
-methyl ester	48	52
4-*tert*-butylphenyl ester	98	155
-pentyl ester	48	48
-nonyl ester	53	53
2-propynyl ester	53	67
2-hydroxyethyl ester	43	58
4-cyanophenyl ester	65	123

$P = 0.05$; s.e. ±7.0.

Table 2 shows the range of activity of dikegulac-sodium. Growth retardation was seen in a wide range of plants, for example, cereals, cultivated and weed grasses and woody plants. The retardation of *Digitaria sanquinalis* Scop. was sufficient for dikegulac-sodium to be considered herbicidal. The compound induced abscission and stimulated ripening, both of which have been reported to be associated with the plant hormone ethylene[4,5]. The test compound also destroyed apical dominance in *Rhododendron simsii* Planch., inducing the production of axillary shoots and increasing the number of flowers on *Gerbera jamesonii* H. Bolus ex Hook. Dikegulac-sodium also induced parthenocarpic fruit set on *L. esculentum* Mill. cv. Tiny Tim.

Of all the monosaccharide derivatives tested so far in our laboratory, only the diketal analogues of 2-ketogluconic and 2-ketogulonic acids have shown interesting plant growth regulatory activity. Large scale tests have indicated that the most promising effects are the growth retardation and inhibition of apical dominance in woody plants, for example, *Liqustrum vulgare* L., *Thuja occidentalis* L. and *Rhododendron simsii* Planch. It is as yet too early to speculate on the impact which this group of compounds will have on plant production.

Induction of hormone sensitivity by dehydration is one positive role for drying in cereal seed

THE hydrolysis of food reserves in seeds (usually fats, starch and protein) is closely linked to embryo growth since it does not begin until germination has started. The control of food mobilisation by the embryo is best understood in cereals such as barley and wheat. In these cases the hormone gibberellin, moving from the embryo, activates the aleurone layer to produce an array of hydrolytic enzymes, including α-amylase, protease and β-1,3-glucanase and to secrete them into the endosperm where stored materials are located[1]. The stored food is of course laid down in the grain during its development on the mother plant. But at the time when this accumulation is taking place the grains contain relatively high levels of gibberellin[2]; nevertheless, the food reserves seem free from hydrolytic attack. One possible reason for this is that in undried grains on the mother plant the hormonal control system for enzyme synthesis and secretion does not function. No research has been done directly on this problem; what relevant research there is shows some discrepancies[3,4]. Our results, described here, demonstrate that the hormonal control system operates fully only after the mature grains have been dried. Dehydration is necessary for the development of complete sensitivity to gibberellin.

Barley (*Hordeum distichum* cv. Julia) was grown in the greenhouse from December 1974 to March 1975 with supplementary lighting to give a 16-h daily light period, or in the field at the Lord Rank Research Centre, High Wycombe. Grains were collected approximately 30 d after anthesis. The grains were dehulled (fresh weight 60± 3 mg per seed) and half the sample was left to dry at room temperature for 2 d when a weight of approximately 31 mg per seed was reached (a water content of 9 6%). Embryos were removed from the dried and undried samples and the embryoless grains were sterilised in sodium hypochlorite (1.4% available chlorine) for 20 min. They were then rinsed several times and incubated according to the method of Jones and Varner[5] but with the medium containing chloramphenicol (10 μg ml^{-1}) and nystatin (100 U ml^{-1}). Gibberellic acid (10^{-6} mol l^{-1}) was included in the flasks. Incubation was terminated at different times and the medium was assayed for α-amylase[5] and β-1,3-glucanase[6]. These enzymes were chosen because α-amylase is both synthesised and secreted in response to gibberellic acid, whereas the β-1,3-glucanase requires the hormone only for its secretion. Thus, the two hormone-controlled processes, enzyme synthesis and enzyme secretion, could be studied separately. The aleurone layers were removed from the grains without embryos for extraction of any non-secreted enzymes remaining in the cells.

The results for α-amylase (Fig. 1) show the characteristic hormone-induced enzymatic response in the case of the previously dried grain, but the undried grains fail to respond until after extremely long exposure to gibberellic acid and then to only a small degree. Increased response by undried grains can, however, be provoked by very high gibberellin concentrations but even so, enzyme synthesis and secretion at the level exhibited by dried seeds is never attained (Table 1). The degree of sensitivity of barley aleurone cells to gibberellin therefore clearly depends on previous dehydration of the grain. The findings suggest that there would be no appreciable breakdown of starch during its accumulation in the developing grain as the hormonal control system for enzyme production would be inoperative. The biological importance of this is clear. The practical implications are connected with the spoilage of dried cereal grain when this is rewetted before harvesting; here, hormone-controlled enzyme production can occur, leading to starch hydrolysis.

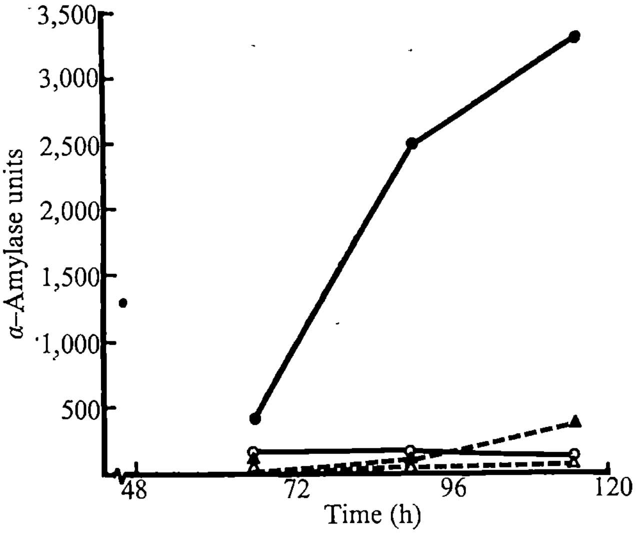

Fig. 1 α-Amylase production by dried and undried half grains. Ten half grains were incubated for appropriate lengths of time in 2 ml of medium. After incubation, medium was decanted, half grains were washed with 2 ml of buffer and washings were added to medium. After centrifugation supernatant was assayed for secreted enzyme. Aleurones were removed from washed half grains and homogenised in 4 ml of buffer. After centrifugation supernatant was assayed for non-secreted enzyme. ———, Dried grains; – – – –, undried grains; ● and ▲, secreted enzyme; ○ and △, non-secreted enzyme.

The pattern for β-1,3-glucanase is different, however, since dried and undried grain show only slight differences in total enzyme (Fig. 2) but drying does have some relatively small effect on the gibberellin-sensitive secretory mechanism. Thus the indication is that secretion can function almost fully even in seeds which have not been dehydrated. The results for

Fig. 2 β-1,3-Glucanase production by dried and undried half grains. Half grains were incubated and enzymes extracted as described for Fig. 1. Symbols as in Fig. 1.

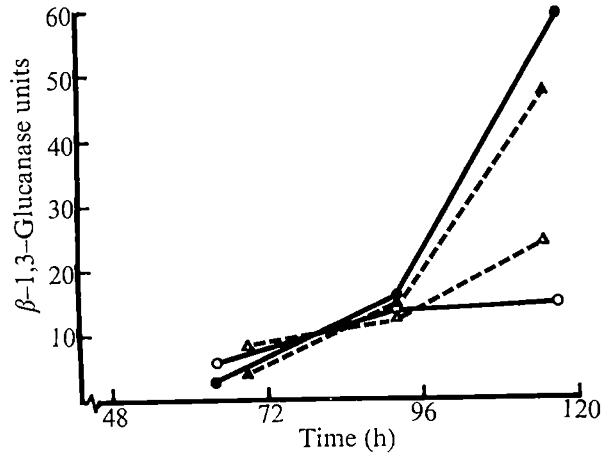

Table 1 Effect of gibberellic acid concentrations on α-amylase secretion in undried grains

Gibberellic acid concentration (mol l^{-1})	α-Amylase units (per 10 embryoless grains)
10^{-6}	420
10^{-5}	900
10^{-4}	1,000

Ten half grains were incubated for 114 h in 2 ml of medium containing various concentrations of gibberellic acid. After incubation, medium was decanted, half grains were washed with 2 ml of buffer and washings were added to medium. After centrifugation, the supernatant was assayed for enzyme activity.

α-amylase and β-1,3-glucanase together indicate that previous drying is required probably only for hormone-induced synthesis (for example, α-amylase) and not for enzyme secretion.

The control of hormonal sensitivity by dehydration is matched by the effect of this treatment on germination itself[7]. In our experience undried, intact grains as collected for the above experiments do not germinate, but when dried for 2 d the rewetted seeds germinate within only 3 d at 20 °C.

In all, our results demonstrate the critical importance and positive role of dehydration in the physiology of a cereal seed. These findings demonstrate (apparently for the first time) how the full operation of a hormonal system in a plant tissue is instigated by previous drying. As far as the biology of seeds is concerned we should see this as a device for retaining the integrity of the food reserves until dispersal from the mother plant has been achieved. Together with this, the continued growth of the embryo (that is, germination) is restrained and can recommence only after drying has been experienced. The physiology of these two aspects of the controlling role of dehydration may be basically the same, connected with the regulation of the synthesis of enzymes, in one case for food reserve hydrolysis, in the other for germination itself. Experiments are in progress to investigate these phenomena further.

Alteration of epididymal sperm transport and maturation in mice by oestrogen and testosterone

THE maturation of spermatozoa during passage through the mammalian epididymis, involves changes in motility, metabolism, morphology, biochemical properties and the development of the ability to fertilise ova[1]. This maturation process, and the maintenance of fertilising ability, is dependent on androgen[2]. When testosterone levels are lowered by castration or hypophysectomy, sperm from the cauda epididymis have immature acrosomes (guinea pig)[3] and lowered fertilising ability (rat)[4]. These effects are prevented by testosterone treatment. Since reduction of testosterone levels enhances the rate of epididymal sperm transport[4,5], the incomplete maturation could result from spermatozoa spending insufficient time in critical regions of the epididymis, as well as from a decreased ability of the epididymis to promote sperm maturation. We demonstrate here that oestrogen and testosterone affect one aspect of sperm maturation in mice by altering the rate of epididymal sperm transport, and also affect fertility.

Male BC3F$_1$ hybrid mice were injected daily with either 10 μg d^{-1} oestradiol benzoate (OB), 80 μg d^{-1} testosterone propionate (TP), both hormones (OB+TP) or sesame oil alone. Administration of these hormones for up to 50 d produced negligible effects on the process of spermatogenesis in the testis (Table 1, Fig. 1). This observation is not inconsistent with other studies; the inhibition of spermatogenesis in mice by oestrogens is strain dependent[7].

Table 1 Sperm content of testes, epididymides and vasa deferentia of hormone-treated mice (sperm heads per mouse $\times 10^{-6}$)

	Control	OB	OB+TP
Testes	51.6±1.9	51.9±1.7	47.2±2.1
Capita epididymides	20.6±0.8	1.4±0.2*	7.2±0.4*
Corpora epididymides	6.7±0.8	2.0±0.2*	3 8±0.2*
Caudae epididymides	49.2±1 4	10.8±1.3*	27.8±1.0*
Vasa deferentia†	3.6±0.6	4.0±0.6	2.9±0.4

BC3F$_1$ male mice (C57BL ♀×C3H ♂ from Cumberland View Farms, Clinton, Tennessee) were injected daily with hormone given intramuscularly in the leg in 0.05 ml of sesame oil for 39–50 d. Oestradiol benzoate (OB) was obtained as Oestroform (British Drug Houses); testosterone propionate (TP) as Perandren (Ciba). The sperm contents of these organs were determined by counting the number of sperm nuclei ('sperm heads') in sonicated tissue homogenates in a haemocytometer. The spermatid nucleus becomes resistant to sonication at late step 12, and remains sonication resistant throughout further maturation[6]. The sperm heads were prepared by homogenisation of the tissue in distilled water with a Polytron homogeniser, sonication and filtration through 10-μm pore nylon cloth, to remove debris.

* Significantly different from controls at $P<0.01$.

† In other experiments, OB significantly reduced the number of sperm in the vas, as well as in the epididymis, while having little effect on number of sperm in the testis.

In contrast, the sperm content of the epididymis was markedly reduced by OB treatment (Table 1). Treatment with OB+TP produced a smaller reduction. TP alone had little effect. Except for the decrease in sperm content and for a small, but significant, reduction in the height of the epithelial cells, the histological appearance of the epididymis was unchanged by OB treatment.

The reduced numbers of spermatozoa could result from lower testicular sperm production, resorption of spermatozoa in the epididymis, or an enhanced rate of sperm transport through the epididymis. Testicular sperm production was calculated by dividing the number of sonication-resistant sperm heads (Table 1) by the time span (5.9 d)[6] from late step 12 through further maturation[8]. Similar values of 8.7×10^6, 8.8×10^6 and 8.0×10^6 sperm d^{-1} were obtained for control, OB and OB+TP treated mice, respectively.

Experiments with mice, unilaterally vasectomised for 6–10 d, demonstrated that resorption of sperm in the epididymis is negligible. The accumulations of spermatozoa in the ligated-side epididymides of these mice were 11×10^6, 6.3×10^6 and 6.8×10^6 sperm d^{-1} for the 2 epididymides in control, OB and OB+TP treated mice, respectively, closely matching the sperm production rates. In addition, the reduction in the total radioactivity of the sperm in the reproductive tract, which occurred between days 27 and 31 in OB treated mice as the radioactively labelled sperm passed out of the vas, was largely prevented by ligation of the vas.

The kinetics of the transport of spermatozoa from the testis through the epididymis and the vas deferens was studied by measuring the radioactivity in cell suspensions or in sperm nuclei from different segments of the reproductive tracts of mice,

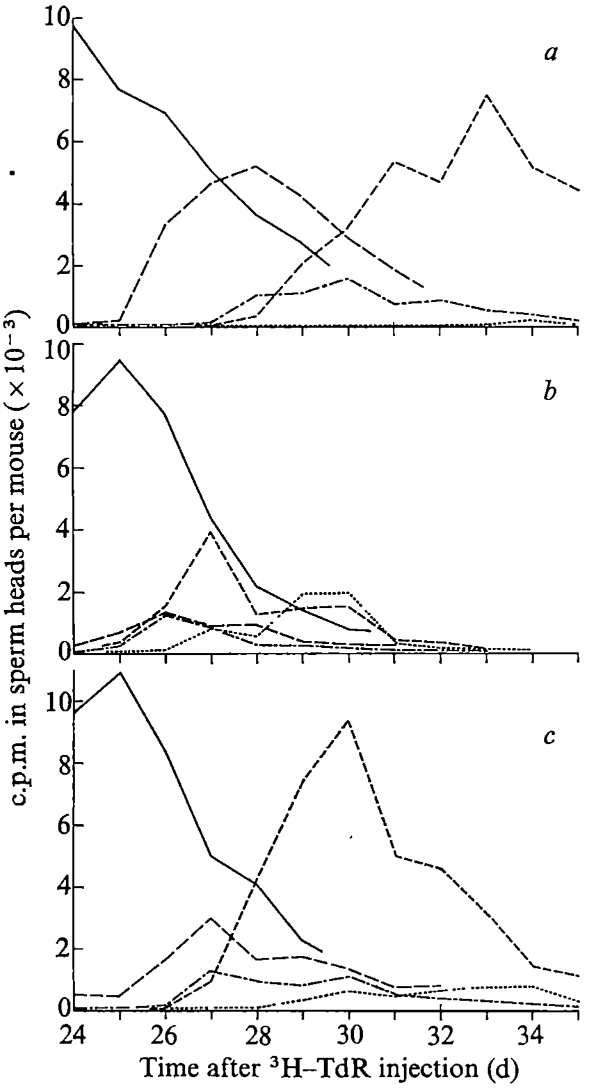

Fig. 1 Passage of radioactively labelled spermatozoa through the male reproductive tract of control (*a*), OB-treated (*b*) and OB+TP-treated (*c*) mice. Mice were given daily injections of the indicated hormone. On day 15 of hormone treatment, they were injected intraperitoneally with 30 μCi of ^{3}H-thymidine (TdR). Sperm heads, prepared from the testis (———), caput (— —), corpus (— - —), cauda epididymis (- - -) and vas deferens (···) of mice killed on the indicated days, were collected by filtering onto Whatman GF/C filters. The radioactivity in the sperm heads was determined by liquid scintillation counting (30% efficiency). Data points (except for day 35) are averages of 3 samples, each prepared from one mouse. The average fractional standard errors in the counts between animals were 0.11, 0.15, 0.22, 0.24, 0.26 for the testis, caput, corpus, cauda epididymis and vas deferens respectively.

killed at daily intervals after injection of ^{3}H-TdR. The radioactivity in the testis was constant for 25 d after the administration of ^{3}H-TdR (data not shown), and then decreased similarly in all experimental groups (Fig. 1). In control and TP-treated mice, radioactive spermatozoa first entered the caput epididymis on day 26, the corpus on day 28, the cauda on day 29, and the vas not until day 34, or later. In OB and OB+TP-treated mice, however, radioactively labelled spermatozoa were present in the vas deferens on days 27 and 29 respectively.

The epididymal transit times calculated from these profiles clearly show a marked reduction with OB treatment and a less marked reduction with OB+TP treatment (Table 2). The reductions in epididymal sperm counts are a result of this increased transport rate, since transit times calculated from the sperm counts are nearly identical to those from radioactivity profiles.

Table 2 Average epididymal transit times in hormone-treated mice (d)

Epididymal segment	Control	OB	OB+TP
Caput	2.3*(2.4)†	0.8 (0.2)	1.5(0.9)
Corpus	1.6 (0.7)	−0.1 (0.2)	0.5 (0.5)
Cauda	⩾5.8 (5.6)	1.2 (1.2)	1.8 (3.6)

* Calculated from radioactivity profiles (Fig 1). The average transit time for a given segment is the difference between the times at which labelled spermatozoa enter that segment and enter the next segment (start of rise of curves), or, equivalently, the difference between the times the spermatozoa leave the previous segment and leave that segment (maxima of curves) Unbiased estimates of these times were obtained by computer fitting the curves with exponential functions (manuscript in preparation). All values are averages of determinations from the times of entry and of leaving. For the control cauda epididymis, lower limits were chosen assuming labelled spermatozoa enter the vas after day 35.

† Calculated from sperm counts (Table 1). In the absence of sperm resorption, the same number of spermatozoa per day must pass through each point in the reproductive tract and that number equals the testicular sperm production rate (S) The number of spermatozoa present in any segment (n), equals the rate of entry of spermatozoa (S) times the average time a spermatozoon spends in that segment (t), which is the transit time. Therefore, $t = n/S$.

Experiments were then performed to determine if one aspect of sperm maturation, disulphide crosslinking of the sperm nuclear protein[9], was affected by the hormonal treatment. Mouse sperm nuclei show progressive maturation during passage through the epididymis (Table 3). Sperm nuclei from each epididymal region of OB-treated mice were, however, less mature than those of control mice. This was not a direct result of OB treatment on sperm maturation, but rather a consequence of the enhanced rate of transport. Spermatozoa, blocked, by vasectomy, in the cauda epididymis and proximal region of the vas deferens of the OB-treated mice, showed increased disulphide crosslinking. This aspect of sperm maturation is time dependent, not necessarily dependent on the epididymal milieu, as expected from previous observations[9].

The crucial aspect of sperm maturation is the development of fertilising ability. We tested mice, given hormonal treatment for 28 d before and during mating, by placing each male with two virgin females for two weeks. The males were then killed, and showed epididymal sperm counts, unaltered by mating. The females who did not bear litters were killed 14 d later, and checked for the presence of embryos. Nine out of nine control mice were fertile, but only two out of nine OB+TP-treated mice were fertile. All nine mice injected with OB were sterile. The fertility of the treated mice is significantly below that of controls ($P<0.005$). Vaginal plugs were seen in females in all experi-

Table 3 Effect of hormonal treatment on sperm head maturation, measured by times (min) of incubation in SDS–DTT required for swelling

Source of sperm heads	Control	OB	OB+TP
Caput epididymis	12±1	2	—
Cauda epididymis	21+1	11±1*	20±0.3
Vas deferens	26±0.5	19±1†	—
Cauda-proximal vas from vasectomised mice			
Control side	26	12±1	—
Vasectomised side	22	30±3*	—

All mice were killed after 45–47 d of hormone treatment. Several mice were unilaterally vasectomised after 40 d of hormone treatment by ligating and cutting the vas deferens.

The extent of formation of disulphide linkages in the sperm nucleus was determined by the rate of swelling in 1% sodium dodecyl sulphate (SDS) and 2×10^{-3} M dithiothreitol (DTT) in 0.05 M sodium borate buffer (pH 9.0)[9]. Sonicated sperm heads were suspended in SDS–DTT and observed microscopically during incubation at room temperature (24±1 °C) from 2 to 30 min The level of swelling was scored on a 0–4 scale, and the time required to reach the level of 2 was determined by interpolation.

* Significantly different from controls at $P<0.01$. In vasectomised mice, the statistical comparison was made between vasectomised and control sides.

† Significantly different from controls at $P<0.05$.

mental groups. Further experiments are needed, however, to determine whether the infertility of OB-treated mice is a result of the immaturity of the sperm, or some other effect of the treatment.

The enhancement of epididymal sperm transport by oestrogen is a novel finding. The slowing of sperm transport by testosterone had been reported previously in the rat using ligation of the efferent ducts and/or vas deferens[4,5]. Here, we confirm this phenomenon in mice without using ligation, which might perturb fluid and blood flow. The mechanisms responsible for sperm transport and its hormonal regulation are not known. Possibilities include peristaltic contraction of the epididymal tubules and action of the ciliated cells of the epididymal epithelium[10]. These mechanisms, however, seem to be inconsistent with our findings, since testosterone enhances epididymal contractions[10] and the size of stereocilia[11]. Our observation that the effect of OB is decreased by additional treatment with TP, indicates that OB may act to interfere with either the endogenous production or action of androgen. Oestrogen can reduce testosterone production by direct action on the Leydig cells, or by inhibiting the secretion of luteinising hormone[12]. Morphological changes in the Leydig cells, which accompany depression of luteinising hormone levels[13], were, however, not observed in OB-treated mice. Alternatively, oestrogen can act directly on the epididymis to reduce the effects of testosterone[14], either by competitive binding to a testosterone receptor[15], or by binding to an oestrogen receptor[16] to produce a change opposite to that of androgen.

The results presented suggest the possibility of the regulation of male fertility with oestrogenic or antiandrogenic hormones. Such hormones could, without affecting testicular function, act on the epididymis to enhance the rate of sperm transport, resulting in immature spermatozoa in the ejaculate.

Supported by grants from the Canadian MRC, Canadian National Cancer Institute, the Population Council, USNIH and a contract from the National Center for Toxicological Research. We thank Vincent Eng, Betty Reid and Rudolf Furrer for technical assistance and Dr L. Milas for vasectomising the mice.

Reduced deformability of erythrocyte membranes from patients with Duchenne muscular dystrophy.

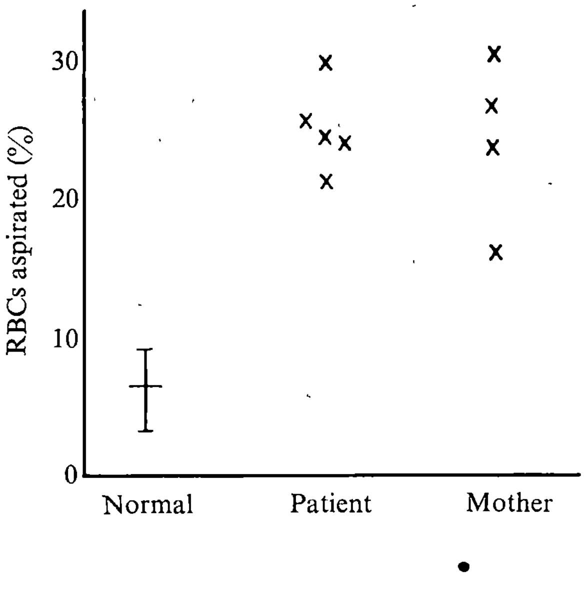
THE fundamental defect in Duchenne muscular dystrophy is obscure. Early investigators attributed the disorder to a primary defect of the skeletal muscle itself,[1] but alternative suggestions have implicated the motor neurone[2,3] or the vascular supply[4]. Recent attention has been directed to the plasma membrane of muscle as well as of other tissues. Several authors have postulated a generalised membrane defect as the fundamental problem in this disorder[5–7].

Matheson and Howland[6], using a scanning electron microscope, examined the erythrocytes of patients with various forms of muscular dystrophy. When compared with control erythrocytes, the patients' cells exhibited striking alterations in surface contour. These changes were most prominent in cells derived from Duchenne patients. The obligate female carriers for Duchenne dystrophy also showed similar deformities of the erythrocyte surface. It is clear that these surface changes are not specific for the muscular dystrophies as such changes have also been noted clinically in association with severe liver disease, uraemia, splenectomy, haemoglobinopathies and β-lipoprotein deficiency. It was previously noted by Weed and Chailley[8] that similar erythrocyte alterations could be induced in 'normal' erythrocytes by incubation in the presence of the divalent cation, calcium, or in solutions whose *p*H exceeded 8.5. The resulting cells, echinocytes, have also been produced following incubation of erythrocytes in the presence of a variety of chemical compounds including salicylates, barbiturates, and 2,4-dinitrophenol.

On the basis of observations of Matheson and Howland, we speculated that the altered surface contour of the Duchenne patients' erythrocytes may be reflected in abnormal membrane elasticity or deformability. To evaluate this property, we have used cell elastimetry modified from the original method of Mitchison and Swann[9]. This method has been used successfully in our laboratory in the study of polymorphonuclear leukocytes[10] and was readapted readily to the study of erythrocytes.

Heparinised blood was obtained by venipuncture and the plasma removed by centrifugation. The cells were then washed three times in a balanced salt solution at *p*H 7.2. Micropipettes were pulled to an internal diameter of 1–2 μm and attached to a sensitive source of negative pressure. With microscopic assistance, a micromanipulator was used to direct an erythrocyte to the pipette orifice. The amount of negative pressure

Fig. 1 Percentage of erythrocytes aspirated at negative pressures greater than 100 mmHg in preparations from controls, Duchenne dystrophy patients and obligate female carriers.



required to aspirate the erythrocytes into the pipette was determined. Measurements were not carried beyond negative pressures of 250 mmHg even though some cells were not aspirated at negative pressures exceeding 500 mmHg. The negative pressure required to aspirate an erythrocyte into the pipette could depend either on the fluidity of the cytoplasm or the plasma membrane. The latter seems more likely since red cell ghosts have been shown to exhibit the same deformability characteristics as intact erythrocytes[11].

Negative pressure measurements were carried out on 100 red cells from each control or patient and the percentage of cells aspirated at negative pressures in excess of 100 mmHg was computed.

We have used this technique on erythrocytes from five patients with Duchenne muscular dystrophy and four obligate female carriers. All diagnoses were substantiated by abnormal serum creatine phosphokinase (CPK) levels, muscle biopsy findings, and genetic analysis.

Of the Duchenne dystrophy erythrocytes, 25% were aspirated at negative pressures greater than 100 mmHg compared with only 6% of control erythrocytes (Fig. 1). It is interesting that erythrocytes from obligate female carriers exhibited a comparable reduction in deformability. Both observations are highly significant (Student's *t*-test).

The relevance of these observations may be considered from two perspectives. First, in terms of deformability, erythrocytes from Duchenne patients are easily distinguished from control cells as are those from the obligate female carriers. Since the measurement of serum CPK levels fails to delineate carriers consistently, the biological assay used in this study may offer an effective adjunct for carrier detection, and thus, for genetic counselling.

Second, and more fundamental, is the relevance of altered erythrocyte deformability in Duchenne dystrophy. To address this question, it is important to examine the mechanism of this deformability. Phagocytic cells, including PMNS have a recognisable microtubule–microfilament system distributed beneath the plasma membrane. Abundant data indicate that this system involves contractile proteins similar to, if not identical with actin and myosin. Recent evidence from our laboratory has indicated an association between membrane deformability and microtubule–microfilament function in PMNs[12]. Although erythrocytes lack a microtubule system as such, proteins with a fibrillar appearance have been demonstrated on the cytoplasmic surface of the red cell membrane. These proteins are myosin- and actin-like and exhibit ATPase activity characterised as ouabain insensitive and divalent cation dependent[13,14]. These properties are analagous to those of myo-fibrillar ATPase and to mitochondrial ATPase. This association of ATPase activity with fibrillar proteins on the inner surface of the red cell membrane provides a reasonable basis for understanding the process of erythrocyte membrane elasticity or deformability.

The observations of this study support the present notion of a generalised membrane defect in Duchenne dystrophy and suggest that further studies of the biochemical events associated with the dynamic process of red cell deformability may well explain the basic defect in this disorder.

We thank Mr Kenneth Myers for technical assistance and Ms Miriam Hooper of the Los Angeles Muscular Dystrophy Association for referring the patients. This work was supported by grants from the NIH.

Enhanced *Trypanosoma musculi* infections in mice with concomitant malaria

A PHASE of immunodepression is characteristic of experimental malaria infections and, in mice, immune responses to antigens as diverse as sheep red blood cells[1], tetanus toxoid[2], oncogenic viruses[3] and *Toxoplasma gondii*[4] are diminished. From immunological and epidemiological viewpoints it is important to know what happens when animals are infected with another agent during this period of immunodepression. The agent must be carefully chosen; it must be able and likely to coexist with the malaria parasite *in vivo*, be easy to monitor and elicit a well defined immune response *Trypanosoma musculi*, an avirulent murine trypanosome, fulfils these criteria. There is no cross

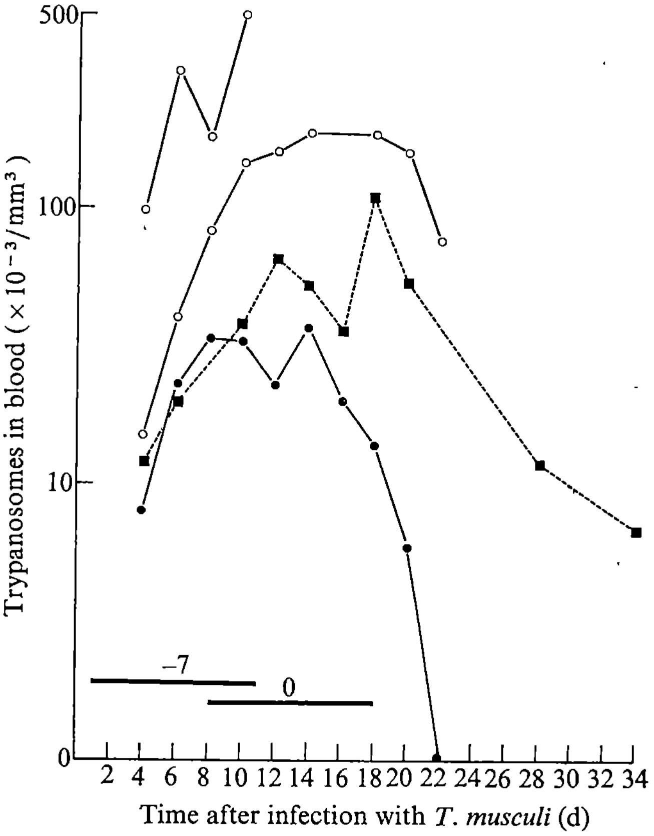

Fig. 1 Patterns of infection with *T. musculi* in female TO Swiss mice Each point represents the mean of all control mice (●), mice infected with *P. yoelii* at the same time (■) and mice infected with *P yoelii* 7 d earlier (○). This last group has been divided into subgroups; in one of these 5 mice died of trypanosomiasis within 10 d whereas the remaining 13 survived for at least 21 d. The graph is incomplete because the death of some mice after day 22 and the fact that some mice had recovered from their infections while others still harboured parasites, would give a false impression of the nature of the infection during its final phase if the mean parasitaemias were plotted. This latter point also applies to the other experimental group. The solid blocks, −7 and 0, indicate the periods of immunodepression related to infection with *P. yoelii* 7 d before *T musculi* and at the same time.

immunity between it and rodent malarias[5], the immune response has been very carefully characterised[6–8] and the progress of the infection can be monitored easily by taking minute quantities of blood. We have found that *T. musculi* infections are considerably enhanced in mice coincidentally infected with an avirulent malaria parasite, *Plasmodium yoelii* (*P. berghei yoelii*)[9].

Batches of mice were infected intravenously with approximately eight *P. yoelii* parasites and challenged by the intravenous injection of about 1,000 *T. musculi* at the same time or 7 d later. The trypanosome infections were monitored and the results are shown in Fig. 1. Infections in 18 control mice resembled those described by Viens *et al.*[6] and the mice overcame the infections within 22 d. In all the experimental animals, the infections were more intense and persisted for longer than in the controls. The greatest enhancement occurred in mice infected with *P. yoelii* 7 d earlier. In this group, 5 out of 18 mice died of trypanosomiasis within 10 d, one mouse harbouring over 5×10^5 trypanosomes per mm^3 of blood just before it died. Of the remaining mice, a further four died on days 22–24 of a combination of malaria and trypanosomiasis, two died of recrudescent malaria 25 and 26 d after infection while still harbouring some trypanosomes and seven became negative between days 21 and 28. In 18 animals infected with *T. musculi* and *P. yoelii* at the same time the infections resembled those in control mice until day 10 but thereafter they continued to rise for a further 7–9 d before gradually declining until all the mice were negative on day 41. There were no fatalities in this group.

Immunodepression during *P. yoelii* infections coincides with the peak of parasitaemia and lasts for about 10 d (ref. 1). In mice infected with *P. yoelii* 7 d before *T. musculi* this period of immunodepression would have occurred during days 1–11 of the trypanosome infection, just when the control animals were beginning to overcome it. In mice infected with *P. yoelii* at the same time as *T. musculi* the period of immunodepression would have extended over days 8–18 and this is consistent with the observation that it is during this period that the infections in the experimental mice diverge from those in the controls.

Immunity to *T. musculi* has been shown to operate in two stages[6–8]. The first response after about 6 d inhibits reproduction and involves T-cell dependent ablastin and T-cell independent trypanocidal antibody. The second response brings about the elimination of the trypanosomes and is T-cell dependent. In T-cell deprived mice, *T. musculi* infections persist for the lifetime of the host[6]. This was not the case in our experiments and our results indicate that *P. yoelii* produces a defect in the first response. There is, as yet, no satisfactory explanation of immunodepression during malaria infections but a hypothesis which suggests that antibody producing cells, particularly those responsible for IgM, are affected is consistent both with our findings and with the well known fact that cells forming plaques to sheep red blood cells are considerably reduced during *P. yoelii* infections[1].

The epidemiological significance of immunodepression during malaria is considerable because the chances of transmission of a superimposed infection increase as the intensity and duration of that infection increase. There are also reciprocal effects between these parasites. In these experiments we have noted that *P. yoelii* infections are enhanced in some, but not all, mice infected with *T musculi* with the result that mice may die unexpectedly from recrudescenses of malaria or from the cumulative effect of the dual infection. We have also observed that the piroplasm *Babesia microti* enhances *T. musculi* infections and that both *P yoelii* and *B. microti* modify *T. brucei* infections.

T-cell activation in murine malaria

THE immune response of rodents to malaria is thymus dependent. *Plasmodium berghei* infections are more severe in neonatally thymectomised rats than in intact controls[1], whereas *P. yoelii (P. berghei yoelii)* infections which are self-resolving in normal CBA mice prove fatal in T-cell deprived CBA mice (Jayawardena *et al.*, unpublished) or congenitally athymic nude mice[2]. Malarial infections are also known to depress immune responses to certain antigens. In the mouse, they reduce the antibody[3] and splenic plaque forming cell[4] response to sheep red blood cells (SRBCs), render animals more susceptible to lymphomagenic viruses[5], and severe long term infections prolong xenogeneic skin graft survival time[6]. It has been suggested that such impaired immune reactivity reflects defective lymphocyte or macrophage function, but there has been no unequivocal evidence in support of these possibilities.

We have examined the T-cell mitotic response, the production of anti-parasite antibodies and parameters of T-cell function (the response to phytohaemagglutinin (PHA) and oxazolone) in non-fatal *P. yoelii* and fatal *P. berghei* infections in the CBA mouse, and present evidence suggesting that the development of protective immunity and the nonspecific immunodepression can be related to the T-cell response of the host.

We defined the T-cell response to infection in CBA/Lac–CBA/T_6T_6 mouse radiation chimaeras carrying a chromosomally distinguishable population of T cells. To prepare these radiation chimaeras CBA/Lac mice were thymectomised at 7 weeks of age, subjected to 850 rad X irradiation 10 d later, and reconstituted immediately with 5×10^6 femoral CBA/Lac bone marrow cells. Within 20 h of X irradiation, thymus grafts consisting of two thymus lobes from CBA/T_6T_6 neonates were implanted under the kidney capsule[7]. The grafts remained *in situ* for 30 d after which they were removed[8]. Twenty days later, these mice were infected with the 17X strain of *P. yoelii* or the Anka strain of *P. berghei* (all infections were initiated with an intraperitoneal inoculum of 1×10^5 parasitised RBCs) At various times after infection the spleens were removed and processed for cytological analysis[8] and the proportion of dividing cells, known by their chromosome marker to be of thymus graft origin, was determined. (A minimum of 100 dividing cells were scored at each stage of infection)

The patterns of parasitaemia and the T cell mitotic response in the spleens of infected mice are shown in Fig 1. In mice infected with *P. yoelii*, parasites were detected in the peripheral blood within 2 d and peak parasitaemias were recorded on day 10, after which the infection regressed, all mice being aparasitaemic by day 18 Within 4 d of infection (when the percentage parasitaemia was

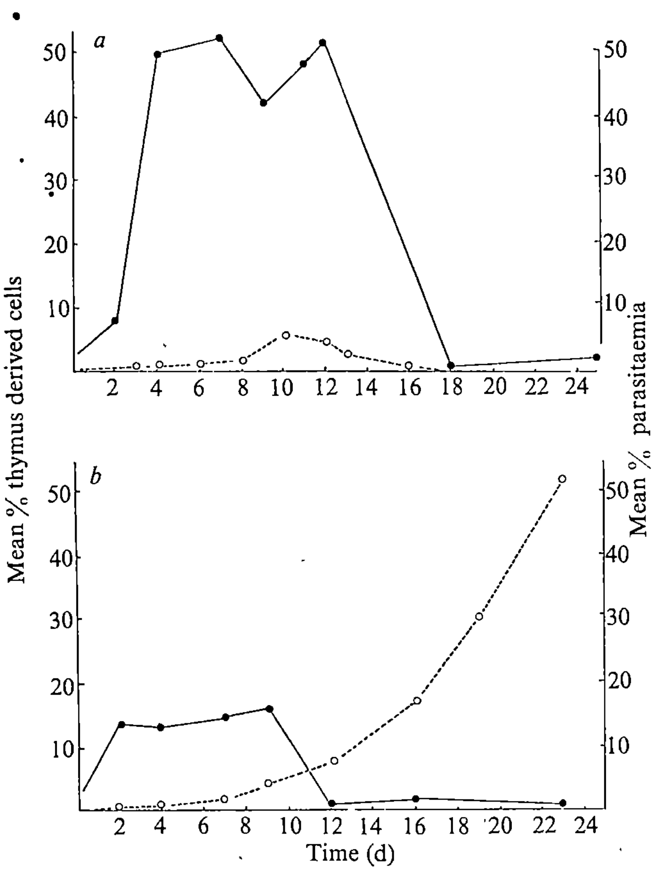

Fig. 1 Mean percentage of thymus graft derived cells (●) dividing in the spleen and mean percentage parasitaemias (○) in CBA/Lac–CBA/T_6T_6 mouse radiation chimaeras infected with 1×10^5 *P. yoelii* (*a*) or *P. berghei* (*b*) parasitised RBCs.

<1%), *P. yoelii* infected mice showed massive T-cell activation—53.1% of the dividing cells in the spleen being of certain thymic origin. This level of T-cell activation was maintained until day 13 Between days 13 and 18, during which time control of the infection seemed to have been achieved, as judged by the clearance of parasites from the peripheral blood, T-cell mitoses became much less frequent.

During the first 10 d of infection with *P. berghei*, parasitaemias were similar to those observed in mice infected with *P. yoelii*. Thereafter the parasitaemias increased steadily and proved fatal by day 24. The amount of T-cell activity elicited during a fatal *P. berghei* infection was proportionately much less than that observed in a resolving *P. yoelii* infection. Although by day 2 13.7% of the cells in mitosis were T cells (compared with 7.4% in *P. yoelii*), there was little change in the level of T-cell activation over the next 7 d and, from day 9 onwards, the response seemed to fail completely in spite of the continuously increasing parasite burden.

The precise functional significance of the T-cell mitosis observed in these infections is uncertain, but such mitosis could be indicative of the development of cytotoxic, helper,

Table 1 Fluorescent antibody titres in CBA mice infected with *P. yoelii* or *P. berghei*. Each determination was carried out on serum pooled from five mice using the indirect fluorescent antibody method for malaria parasites as described by Voller[10]

†Goat anti-mouse IgG_1, IgG_2 and IgM sera were obtained from Nutritional Biochemical Corporation, Cleveland, and were conjugated to FITC[11] isomere 1 (Nordic Pharmaceuticals).

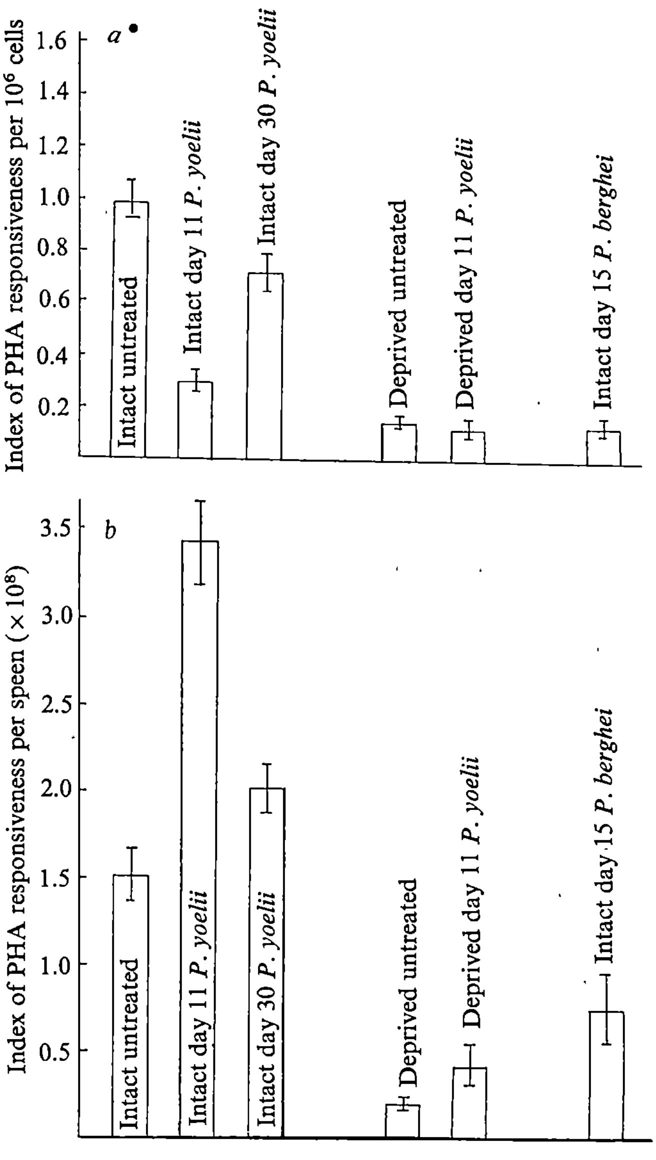

Fig. 2 The index of PHA responsiveness per 10^6 spleen cells (*a*) and the index of PHA responsiveness per spleen±1 s.e. (*b*) in normal and *P. yoelii* or *P. berghei* infected CBA mice. (Uninfected and *P. yoelii* infected T-cell deprived mice were included as additional controls) Each group consisted of five mice The method of quantitation used was that of Doenhoff[13] and is based on the cytological analysis of cells derived from CBA/Lac and CBA/T_6T_6 mice. (Cells of the T_6T_6 strain carry a pair of minute chromosomes by means of which they can be distinguished at metaphase.) A known number of cells from untreated CBA/T_6T_6 mice was mixed with an equal number of cells from CBA/Lac mice whose response to PHA was being determined. The mixture of the two cell types was cultured with PHA (Burroughs Wellcome) for 3 d, when, following metaphase arrest with colcemid, the cells were subjected to cytological analysis[9]. The ratio of the dividing cells from the two sources (Lac:T_6T_6) gave the relative concentration of PHA responsive cells, and this was designated the index of responsiveness per 10^6 cells. (A culture consisted of 1×10^6 cells.) To estimate the degree of responsiveness per spleen, the index per 10^6 cells was multiplied by the total number of nucleated cells in the spleen from which the cultured cells were derived

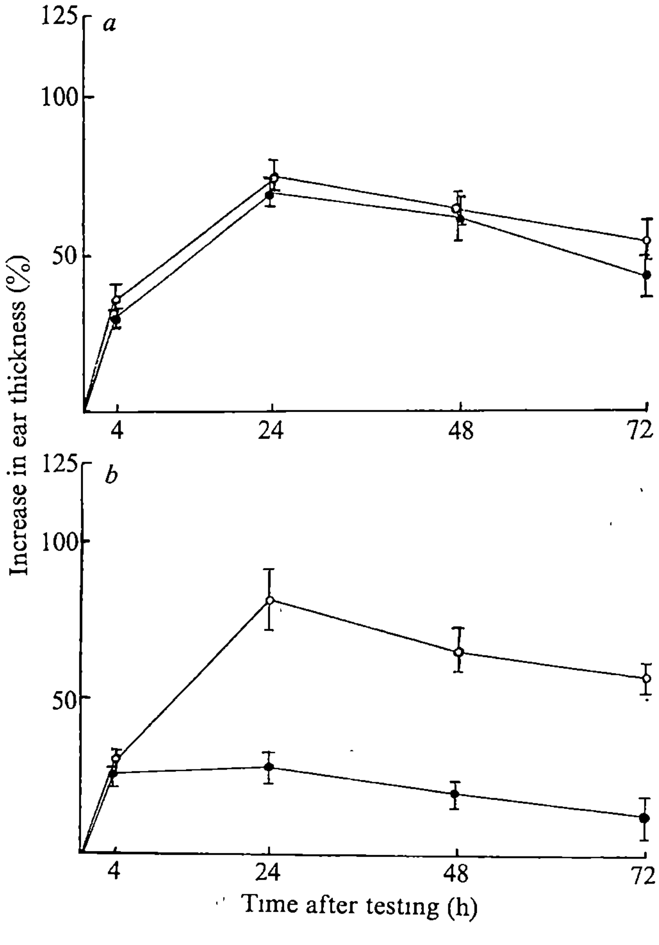
or some other T-cell-dependent effector activity such as lymphokine production. In *P. yoelii* infected mice, considerable T-cell activation occurred early in the infection at a time when only very low levels of antibody could be detected. (Fluorescent antibody levels are recorded in Table 1.) Once the parasitaemia and T-cell activity began to decline, peak levels of antibody were recorded and considerably elevated levels of these antibodies were maintained long after the T-cell response had died down It must be pointed out, however, that this temporal relationship between antibody production and the T-cell response could be due to excess circulating antibody being present only after regression of the blood parasitaemia. *P. berghei* infected mice produced significantly lower levels of antibody particularly in the IgG_1 and IgG_2 subclasses.

In a parallel series of experiments we examined two correlates of T-cell function—the response of spleen cells to the T-cell mitogen PHA[12] (Fig 2), and the response of infected animals to the skin sensitising agent oxazolone (Fig. 3) On day 11 of infection (the time of peak parasitaemia), *P. yoelii* infected mice showed a reduction in the proportion of PHA-responsive cells in the spleen. By this time, however, spleen cell numbers had increased from 1.53×10^8 on day 0 to 12.22×10^8. Thus, when the response was computed on a per spleen basis there seemed to be no absolute deficiency in PHA responsiveness—the response per spleen in the infected group being 3.42×10^8 compared with 1.51×10^8 in the controls. Thirty days after infection, both the proportion and total number of PHA-responsive cells in the spleen showed no significant difference from control values In contrast, *P. berghei* infected mice, when assayed on day 15 of infection, showed a severe reduction in the proportion of responsive cells comparable with that found in T-cell deprived mice and, even when calculated on a per spleen basis, the response was still significantly depressed. The ability to respond to oxazolone was also seriously impaired in *P. berghei* infected mice, whereas the response of *P. yoelii* infected mice, at the time tested, seemed normal.

Fig. 3 Mean percentage increase in ear thickness ± 1 s.e. in uninfected (○) and *P. yoelii* (*a*) or *P. berghei* (*b*) infected (●) CBA mice sensitised with oxazolone (five mice per group). Mice were sensitised (on day 8 of infection) by applying 0.1 ml of a 3% solution of oxazolone in alcohol to the skin of the abdomen and were tested 6 d after sensitisation by applying one drop of a 1% solution of oxazolone in olive oil on to both sides of the right and left ears[14]. Ear thickness was measured at 4, 24, 48 and 72 h after application of the test solution.



It can thus be seen that these two parasites exert very different effects on the T-cell pool; *P. yoelii* induces massive T-cell activation, the development of protective immunity and the responses to PHA and oxazolone seem normal. *P. berghei*, on the other hand, elicits limited T-cell activity—there being a failure of the T-cell response to the parasite and a generalised failure of T-cell function. Although transient depression of immune responsiveness to antigens such as SRBC, HGG (heat aggregated human γ globulin)[4] and tetanus toxoid[15] have been shown to occur *P. yoelii* infections—this is not necessarily due to suppression of T-cell function. Architectural changes in the spleen and consequent changes in cell relationships, dilution of responsive cells by non-responsive elements or some form of preemption[16] may be relevant to this temporary loss of immune responsiveness and may also contribute to the immuno-suppression in *P. berghei* infections.

Although it is not possible on the basis of the results presented here to establish definitely a causal relationship between T-cell activity and the development of immunity or the nonspecific suppression of T-cell function, these results suggest strongly a crucial role for T-cell activation and T-cell suppression in the pathogenesis of malaria.

Genetics of natural resistance to herpesvirus infections in mice

INHERITED resistance to virus infections has been demonstrated in several murine systems[1-6]. Susceptibility to mouse hepatitis virus[3] and resistance to arbovirus[7] infections in mice are dominant traits associated with the capacity of macrophages from the susceptible strains to replicate virus. Resistance to Friend leukaemia virus- and Gross leukaemia virus-induced leukaemogenesis is determined by at least two genes, one closely linked to the immune response genes of the mouse[8]. Conversely, susceptibility to lymphocytic choriomeningitis (LCM) virus infections in mice has been associated with a gene closely linked to the immune response genes[9]. The latter seems to be associated with the cell-mediated immune response to LCM which causes tissue damage and leads to death. Cell-mediated immunity seems to be important in resistance against herpes simplex virus (HSV) infections[10-12]. Analysis of the aspects of cell-mediated immunity which might be involved in resistance in man is complicated by the uncontrollable factors associated with activation of latent herpesvirus infections. I have developed a mouse model which has shown that at least three genes are responsible for resistance to HSV. Although preliminary evidence suggests that resistance is immunologically mediated, resistance genes do not seem to be closely linked to the histocompatibility region of the mouse.

We used inbred strains of mice with high and low resistance. Since resistance to viral leukaemogenesis was demonstrated with an unusually virulent strain of virus[13] (Gross passage A[14]), we used an HSV-1 strain (2931) which is highly virulent in BALB/c mice. The strain was isolated from a human labial lesion and passaged ten times in Vero cells. The virus was then cloned to produce a homogeneous virus population, and thus a homogeneous response from the various mouse strains. Cloned virus was typed by the neutralising antibody test with antisera provided by Dr Donald Armstrong, Memorial Sloan–Kettering Cancer Center. A large pool was prepared by infecting Viro cells at a multiplicity of 1 plaque-forming-unit (PFU) per cell and incubating the cells for 24 h at 37 °C. Cells and debris were removed from the supernatant by centrifugation at 150*g* and the virus was stored at −80 °C in 1-ml samples. This preparation had a titre of 1×10^8 PFU ml^{-1} when titred at the beginning and end of the experiments. The same pool was used throughout.

Eleven strains of inbred mice were obtained from Jackson Laboratories and tested for their capacity to resist fatal HSV-1 infections. Adult (3–4-month-old) male mice were inoculated intraperitoneally with the stock pool of HSV-1. Six to twelve mice were inoculated with 0.1 ml containing 1–10^6 PFU per inoculum. Mice were observed for 21 d and an LD_{50} was determined for each strain by the Spearman–Karber method[15] (Table 1). Mice usually showed signs of encephalitis and died 5–10 d after inoculation. AKR, A, BALB/c, and C57BL/6 mice were provided by Dr E. A. Boyse of Memorial Sloan–Kettering Cancer Center to confirm that the resistance observed in the mice from Jackson Laboratories could be observed in the same strains from other sources. LD_{50}s were essentially the same and have been incorporated into Table 1. The eleven strains seem to fall into three categories: resistant, moderately susceptible and very susceptible. Most resistant mice survived inocula of 10^6 PFU of HSV-1, while LD_{50}s for moderately susceptible mice are in the range 200–1,000 PFU per inoculum. The LD_{50}s for very susceptible mice are in the range 10–70 PFU per mouse. Susceptible mice which survived the lower doses of virus were reinoculated 4–8 weeks later with 10^6 PFU of HSV-1. All survived reinoculation, indicating that they had developed resistance.

Table 1 Resistance of inbred mouse strains to HSV-1

Mouse strain	H_2	LD^{50}HSV-1 (P F.U.)
AKR (12)*	k	$10^{1,0}$
SWR (6)	q	$10^{1,0}$
A (12)	a	$10^{1,33}$
DBA (6)	d	$10^{1,83}$
CBA (6)	k	$10^{2,34}$
BALB/c (12)	d	$10^{2,34}$
C3H/He (10)	k	$10^{3,0}$†
C57BR (6)	k	$10^{3,0}$†
C57BL/6 (12)	b	$>10^6$
C57BL/Ks (6)	d	$>10^6$
C57BL/10 (20)	b	$>10^6$

Mice were inoculated intraperitoneally with 0.1 ml of tenfold dilutions of stock HSV-1 pool and observed for 21 d. Mice died with signs of encephalitis usually 5–10 d after inoculation. LD_{50} was determined by the Spearman–Karber method[15].

*No. test per dilution.

†Titrations not clear cut Two C3H and four C57BR mice survived at lower dilutions. Others died as if to yield the LD_{50} noted. In a second experiment, 20 of each strain were inoculated with 10^6 PFU. Sixty per cent of the C3H/Hc and none of the C57BR mice died.

To determine whether this pattern of resistance and susceptibility was the same for other HSV-1 strains, similar experiments were carried out with three further wild strains of HSV-1 as well as with HSV-1 strains obtained from Dr Fred Rapp (through Michael Bernhardt), Dr Barry Bloom and from the American Type Culture Collection (ATCC). The MacIntyre strain (VR_3) is the prototype HSV-1 strain held by the ATCC and has been used in studies of resistance by Nahmias *et al.*[10] and Stevens and Cook[15]. All strains of HSV-1 have the same relative virulence in C57BL/6, BALB/c and A/J mice, as observed for HSV-1 (strain 2931) (Table 2). The exception was strain HEFM[16] which seems to have lost its virulence for mice. HSV-1 (strain 2931) seemed to be more virulent than the other strains and continues to be used for this study.

Table 2 Virulence of HSV-1 strains

Strain (inoculum)	% killed by HSV-1 A/J	 BALB/c	 C57BL/6
2931 (1×10^4 PFU)	100	100	0
A.P. (2.7×10^4 PFU)	100	100	0
1895 (1×10^5 PFU)	100	60	0
MacIntyre (5×10^4 PFU)	100	60	0
Patton (1.67×10^3 PFU)	100	20	0
M D (1.3×10^4 PFU)	60	20	0
HEFM (2.2×10^6 PFU)	0	0	0

Five mice of each prototype strain were inoculated intraperitoneally with 0.1 ml of the seven HSV-1 strains listed. The amounts of virus inoculated is in parentheses. All mice were observed for 21 d and the percentage killed by each virus strain was calculated.

To determine whether resistance is dominant, crosses were produced between resistant and very susceptible mice ($(C57BL/6 \times A)F_1$) and between resistant and moderately susceptible mice ($(C57BL/6 \times BALB/c)F_1$). Twenty of each of these F_1 animals were inoculated with 10^6 PFU of HSV-1 (Table 3). Ninety per cent of the $(C57BL/6 \times A)F_1$ mice and 100% of the $(C57BL/6 \times BALB/c)F_1$ mice survived, indicating that resistance was dominant.

Further crosses were made to determine the number of genes involved in resistance (Table 3). $(C57BL/6 \times A)F_1$ mice were backcrossed to A/J strain mice. Forty-five adult progeny were inoculated with 10^6 PFU of HSV-1 and 34 (75.5%) of these died. If one dominant gene were involved, assuming parental homozygosity, 50% of the mice would have been susceptible. These data indicate that at least two genes are involved in resistance. $(C57BL/6 \times BALB/c)F_1$ mice were backcrossed to BALB/c mice and 37 of these were inoculated with 10^6 PFU of virus. Only three (8%) of these died. This makes the genetic evaluation more difficult and may indicate that four or more genes are involved in resistance. Specific interaction between genes would also make an evaluation of this type difficult.

Resistance to some murine virus infections is determined by

Table 3 Resistance of crosses inoculated with 10^6 PFU HSV-1

C57BL/6 (40*)	90% live
BALB/c (20)	0% live
A (20)	0% live
(C57BL/6 × A)F_1 (20)	90% live
(C57BL/6 × BALB/c)F_1 (20)	100% live
(C57BL/6 × A)F_1 backcrossed to A (45)	25% live
(C57BL/6 × BALB/c)F_1 backcrossed to BALB/c (37)	92% live

Mice were inoculated intraperitoneally with 0.1 ml HSV-1 containing 10^6 PFU. Percentage of mice surviving 21 d was calculated. *No. of mice per test.

genes linked to the major histocompatibility complex of the mouse. Our preliminary results indicate that resistance to HSV-1 is not associated with a particular histocompatibility (H-2) allele. Resistant mouse strains were of H-2^b and H-2^d types. One susceptible and one moderately susceptible strain was also found to be of the H-2^d type. H-2H and H-2I mice were obtained from Dr Boyse to study this question further. These mice are crosses between C57BL/6 (resistant) and A/J strain (very susceptible) mice in which there is a crossover between the K and D ends of the H-2 region. The H-2H strain carries the K (Ir) region of the H-2I (A/J strain) and the D region of the H-2^b(C57BL/6), and the H-2I carries the reciprocal H-2 crossover. If the K region of the A/J strain is associated with susceptibility to HSV-1, as has been shown for susceptibility to viral leukaemogenesis, the H-2H should be susceptible. They were resistant (86%) to 10^3 PFU of HSV-1. Thus either the H-2 region of the A/J strain mice is not associated with susceptibility to HSV-1 or it is being masked by another resistance gene.

We also used congenic mice obtained from Dr Boyse. Eleven C57BL/6 mice into which the H-2^k allele of the AKR strain had been introduced (B6/H-2^k) and five AKR mice into which the H-2^b allele of C57BL/6 had been introduced (AKR/H-2^b) were inoculated with 10^3 PFU of HSV-1. The B6/H-2^k mice were resistant while the AKR/H-2^b mice were susceptible, indicating that the H-2^k allele did not confer susceptibility on C57BL/6 mice and the H-2^b allele did not confer resistance on AKR mice. These studies must be confirmed with more mice and a broader range of inocula. More definitive evidence for an association of H-2 allele with resistance will come from H-2 typing of resistant and susceptible backcross progeny.

Although genes governing resistance to HSV-1 do not seem to be closely linked to the H-2 complex, and thus the immune response genes of the mouse, preliminary evidence indicates that resistance is not a property of the susceptibility of structural cells and is probably mediated immunologically. Embryo fibroblast cultures were prepared from A/J, BALB/c and C57BL/6 mice and inoculated with HSV-1. Virus replicated to the same titre in each monolayer, indicating that resistance was not mediated by the inability of HSV-1 to replicate in structural cells of resistant mice. Preliminary lymphocyte transformation studies with splenic lymphocytes of mice inoculated 5–6 d earlier with HSV-1 indicate that resistant and moderately susceptible mice were capable of a vigorous response whereas very susceptible mice did not respond above control level (C.L. and R. O'Reilly, unpublished). F_1 crosses between resistant and very susceptible mice were also capable of a strong lymphocyte transformation response to HSV-1, indicating that this characteristic is inherited as a dominant trait.

I thank Dr E. A. Boyse for helpful discussions and for the mice, Drs Scheid and Berlinger for reviewing the manuscript, and Steven W. Smith for technical assistance. This work was supported in part by grants from the National Cancer Institute.

Prevention of rabies by vitamin C

MURATA[1] reported on the virucidal activity of vitamin C and stated that vitamin C prevents various virus diseases. Clinical trials by F. Morishige (unpublished) showed that the incidence of transfusion hepatitis was decreased drastically when vitamin C was injected (3–7 g d^{-1}) for 1–2 weeks after blood transfusion, and Murata has pointed out that vitamin C is effective in the therapy of measles and mumps[1]. I have now found that it also helps to prevent rabies.

Guinea pigs, fixed rabies virus and vitamin C (Lek, Ljubljana) were used in the experiments. Five groups of ten test animals and ten control animals were inoculated intramuscularly with 1 ml of a 10% emulsion of rabbit brain containing LD_{50}–LD_{90} of the infectious fixed rabies virus. Treatment of the test animals was initiated 6 h after inoculation, and vitamin C was injected intramuscularly twice a day for 7 d; each dose contained 100 mg per kg body weight. Control animals were injected with saline. The animals were observed for 14 d. Most of those that succumbed to the inoculation became paralysed on the sixth or seventh day. Some became paralysed on the fifth day, and a few others not until the eighth or tenth day.

The frequencies of deaths from rabies in the five groups treated with vitamin C were: 5/10, 2/9, 6/9, 1/10, 3/10. Of the control animals, however, 9/10, 6/10, 9/10, 6/10 and 5/10 died (Table 1). Thus 17/48 (35.42%) of the treated animals and 35/50 (70%) of the controls died of rabies. The χ^2 value for these frequencies is 11.107, so that the difference between the treated and control groups is statistically significant ($P > 0.01$). My results therefore justify the conclusion that vitamin C is effective in rabies prevention. It had no therapeutic effect, however, for in animals which developed paralysis, continued treatment was always ineffective.

Table 1 Frequencies of deaths in guinea pigs inoculated with fixed rabies virus and treated with vitamin C and in the control animals.

Treatment	Deaths	Survivors	Σf
With vitamin C	17	31	48
Controls	35	15	50
Σf	52	46	98

In preliminary experiments, not reported here, lower doses of vitamin C (25 and 50 mg kg^{-1}) were tried in a small group of guinea pigs. These doses were less effective than the high dose used in the reported experiments. To establish the optimal dose of vitamin C, however, exact dose–response experiments will have to be done on sufficiently large groups of animals.

To exclude the possibility that rabbit brain itself contributed in any way towards paralysis and mortality of guinea pigs, another group of 30 guinea pigs was inoculated with 1 ml of a

10% emulsion of rabbit brain which was free of virus. All animals survived an observation period of 14 d without any signs of disease.

Increased insulin binding capacity of liver membranes from diabetic Chinese hamsters

THE first evidence for an abnormality in insulin receptor capacity in pathological states was provided by Kahn *et al.*[1], who found that liver plasma membranes from the obese hyperglycaemic mouse bound only a fraction of insulin compared with membranes from lean littermates. A similar observation was made with lymphocytes from obese insulin-resistant diabetic patients[2]. In lymphocyte cultures the insulin concentration in the medium seemed to determine the binding capacity of the cells[3]. These results suggested an inverse relationship between the number of receptors and the surrounding concentration of insulin, regardless of the tissue sensitivity to the hormone. We have now found greater than normal binding capacity in the diabetic Chinese hamster, which has genetic insulin deficiency, in many ways resembling juvenile diabetes[4].

Table 1 Characteristics of control and diabetic groups and the respective plasma membrane preparations (10 animals in each group)

	Control	Diabetic
Body weight (g)	36 9±0.3	34.8±0.8
Liver weight (mg)	1.45±0.05	1.71±0.04
Blood sugar (mg per 100 ml)	130±6	468±59
5′-Nucleotidase (μmol $\text{mg}^{-1}\times$min)	0.36	0.33
Mg^{2+}-ATPase (nmol $\text{mg}^{-1}\times$min)	179 2	168.8
Recovery of membrane protein (mg per g wet weight)	1.03	0.94

5′-Nucleotidase was measured as recommended by Solyom *et al*[6] Mg^{2+}-ATPase was assayed by measuring the release of ^{32}P-orthophosphate from γ-^{32}P-ATP (ref 7).

Plasma membranes were prepared by the method of Neville[5] from diabetic Chinese hamsters aged 4–5 months and from control animals of comparable age and weight (Table 1). ^{125}I-insulin binding was assayed after incubation for 20 min at 25 °C, membrane-bound hormone was separated from free hormone by centrifugation through silicon oil (W K., R.R , A. Zynamon and K.D.H., in preparation). Figure 1 is a Scatchard plot from a representative experiment. As previously observed in rats, the points fit two curves corresponding to high affinity–low capacity (site I) and low affinity–high capacity (site II) binding sites[8]. The constants derived from this figure are—for site I: control, 4.2×10^{-13}, diabetic, 9.0×10^{-13} mol per mg protein; for site II: control, 1.9×10^{-12}, diabetic, 4.0×10^{-12} mol per mg protein The corresponding affinity constants are approximately 10^{-9} for site I, and 10^{-8} mol l^{-1} for site II, in both groups. Recovery of membrane protein and enzyme markers was similar for both groups (Table 1). Figure 1 shows that the binding capacity for both classes of binding sites (intercept at abscissa) per mg protein is considerably higher in the diabetic animals, whereas there is no apparent change in affinity (represented by the slope). Although other interpretations of nonlinear Scatchard plots, such as negative cooperativity[9], polymerisation of the hormone[10] or heterogeneity of the labelled hormone[11] are possible, the essential observation—of an abnormally high binding capacity in membranes from diabetic hamster—remains the same.

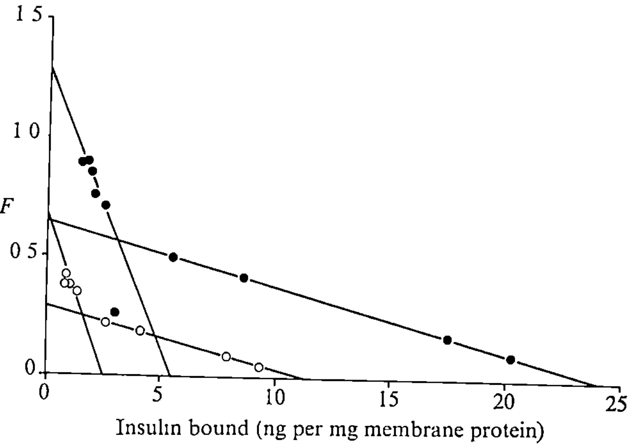

Fig. 1 Scatchard plot of insulin–membrane interaction in two representative preparations from 10 control (○) and 10 diabetic (●) animals. Incubation was performed at 25 °C for 20 min with 0.2 mg of membrane protein per ml and insulin concentrations between 4 and 400 ng ml^{-1}. Insulin degradation was 1.3% in these conditions. Nonspecific binding, that is labelled hormone not displaced by 1 U ml^{-1} has been subtracted.

Severely diabetic Chinese hamsters have abnormally low plasma and pancreatic insulin, a low insulin response to a glucose load and, consequently, low glucose tolerance[4]. Together with a tendency for ketosis[4], these features resemble juvenile diabetes in man, and the diabetic Chinese hamster provides an interesting model for this type of the disease. Apparently the liver adapts to the decreased hormone concentration by raising the number of receptors in the plasma membrane, whereas, conversely, in the hyperinsulinaemic C57BL ob/ob mouse[1] as well as in the KK-mouse[12], the total receptor capacity is lower than normal. Our data therefore support the hypothesis that the hormone level controls the number of receptor sites in the liver cell

Synaptic coupling into the production and storage of a neuronal memory trace

An adequate model for the nature of the memory trace at the neuronal level should provide for a sequence of physiological mechanisms which would include 'read-in' of the neuronal change, 'storage' processes that impart an enduring quality, and 'read-out' of the change in the form of an altered neuronal response to an appropriate neural input. The framework for such a neuronal model seems to be provided by the features of a novel heterosynaptic interaction in a mammalian sympathetic ganglion It had been found previously that one synaptic transmitter (the catecholamine dopamine, DA) could produce a specific and enduring enhancement, lasting for at least several hours, of the subsequent responses to another synaptic transmitter (acetylcholine, ACh)[1]. We have now found that the retention of this DA-induced change can be disrupted by cyclic GMP in a strikingly time-dependent manner that is similar, in principle, to the well known disruptability feature of the memory storage process[2,3]. Additional evidence indicates that the production and storage of the enduring change initiated by DA are mediated intraneuronally by cyclic AMP. We present here a scheme which outlines the cellular pathways postulated to carry out the sequence of events from 'read-in' through to 'read-out'.

The rabbit superior cervical ganglion was studied *in vitro* at ~ 22 °C, in a superfusion chamber with a high resistance sucrose-gap along a section of postganglionic nerve between the recording leads[1]. The section containing the ganglion proper had a volume of 0.3 ml and was perfused continuously with Krebs–Ringer solution at about 1 ml min^{-1}. The test response consisted of the slow depolarisation of the ganglion cells produced by the muscarinic agonist acetyl-β-methylcholine (MCh)[4]. The variable complicating factor of a hyperpolarising component in the response to such cholinergic agonists, which is due to the action of DA released from an interneurone, was eliminated by a pretreatment with the muscarinic agent bethanechol; the latter depletes the ganglion of its functionally-releasable DA[5]. To observe the DA-modulatory action, the slow depolarising response to a test dose of MCh is obtained before and at various times after a brief superfusion with a single supramaximal dose of DA (for example, Fig. 1, compare tracings *a, b* with *c, d*). Enhancement of the cholinergic responses can persist unabated for the duration of the ganglion's survival *in vitro*, that is more than for 3 h.

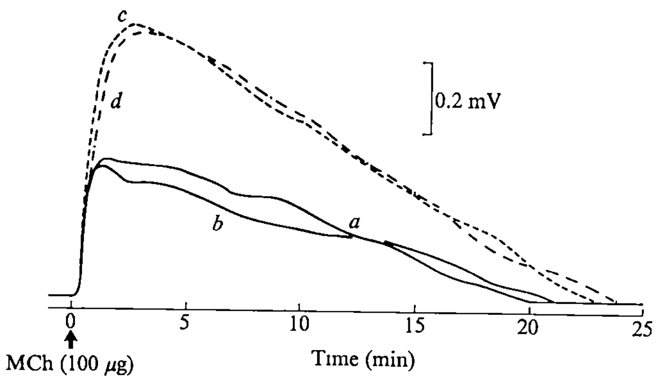

Fig. 1 Modulatory enhancement of methacholine (MCh)-depolarisation after dopamine (DA), and the absence of any effect on this when cyclic GMP was applied 30 min after DA. Each tracing is the slow depolarising response to a single injection of MCh (100 µg). *a* and *b*, Controls before DA *c*, MCh response at 60 min after a single injection of DA (50 µg), with an interposed addition of cyclic GMP (50 µM for 8 min) which began at 30 min after DA. *d*, MCh response at 60 min after a second dose of DA, with no interposed treatment by cyclic GMP.

The usual DA-produced enhancement of the MCh-depolarisations could be prevented if dibutyryl cyclic GMP (50 µM) was temporarily added (for 8 min) to the superfusing fluid. Disruption of the expected modulatory effect could be complete even when the onset of cyclic GMP treatment was delayed for up to 4 min after the DA injection (Fig. 2, compare tracings *a, b* with *c*). A succeeding, second exposure to DA, which was not followed by treatment with cyclic GMP, could still produce the usual later enhancement of MCh-depolarisations (Fig. 2, compare tracing *c* with *d, e*). Guanosine 5′-monophosphate (non-cyclic GMP) could produce some small disruptive effects, guanosine, dibutyryl cyclic AMP and adenosine 5′-monophosphate (non-cyclic AMP) had no disruptive action Additionally, an 8-min treatment with Ringer containing 10 mM K$^+$ simulated the depolarisation that is often elicited by the dibutyryl cyclic GMP itself, but it had no disruptive effect on the DA-modulatory action.

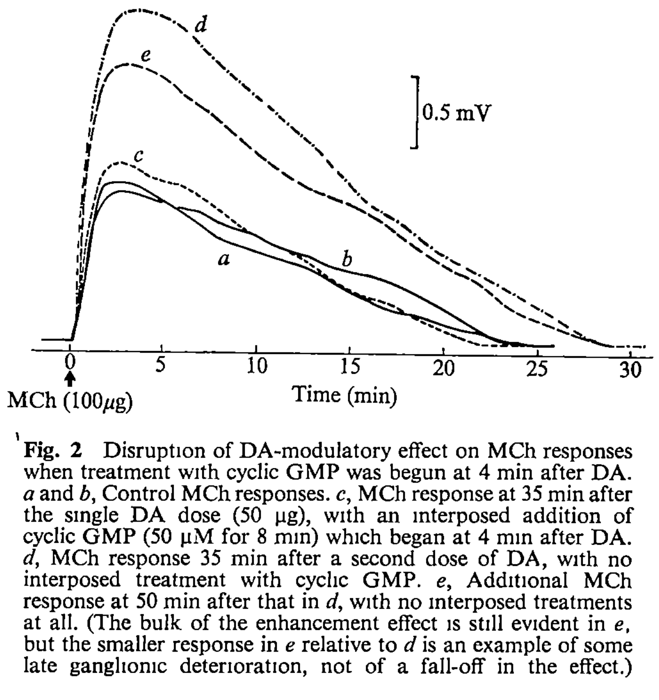

Fig. 2 Disruption of DA-modulatory effect on MCh responses when treatment with cyclic GMP was begun at 4 min after DA. *a* and *b*, Control MCh responses. *c*, MCh response at 35 min after the single DA dose (50 µg), with an interposed addition of cyclic GMP (50 µM for 8 min) which began at 4 min after DA. *d*, MCh response 35 min after a second dose of DA, with no interposed treatment with cyclic GMP. *e*, Additional MCh response at 50 min after that in *d*, with no interposed treatments at all. (The bulk of the enhancement effect is still evident in *e*, but the smaller response in *e* relative to *d* is an example of some late ganglionic deterioration, not of a fall-off in the effect.)

When treatment with cyclic GMP was delayed for periods longer than 4 min after DA, progressively lesser disruptions occurred. With delays of greater than 10–15 min, there was no disruption; that is, retention of the modulatory effect of DA was then unaffected by cyclic GMP (Fig. 1). An initial manifestation of the modulatory enhancing action, which could be observed when DA was injected during a continuous superfusion of MCh (0 5 µM), was also unaffected by the presence of cyclic GMP.

These features of the actions by cyclic GMP suggest that, after the initial modulating change is induced by DA, a 'storage' process develops which leads to a more durable form of modulatory change (see Fig. 3); in this view, the storage process (but not the initial or the durable products) can be antagonised or disrupted by cyclic GMP. On the basis of further evidence (below) we also propose that cyclic AMP is the intracellular mediator for processes I and II in Fig 3, that is, for producing the DA-enhancing action and its 'storage'. This function would be additional to the already proposed role[6–8] for cyclic AMP as a mediator of a direct inhibitory action of DA, which had also been previously described[1,4].

The ability of cyclic AMP to produce an enduring enhancement of the depolarising response to MCh was demonstrated by substituting a treatment with dibutyryl cyclic AMP (1 mM for 6–10 min) for the dose of DA, in

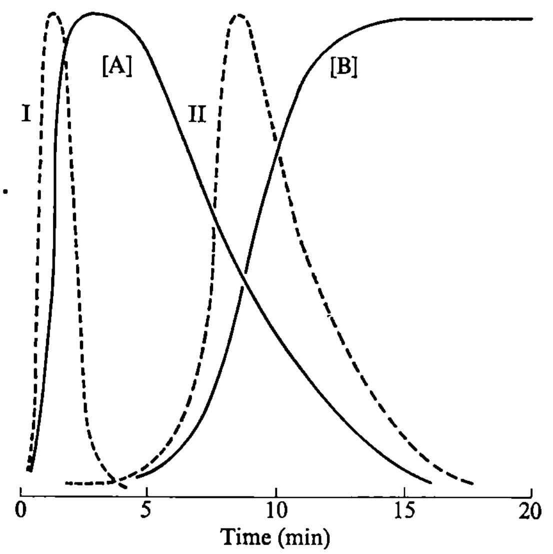

Fig. 3 Time curves for processes and cell products proposed as components in the DA-modulatory action. Process I would involve reactions that lead to the molecular changes which are responsible for the initial enhancement of the slow depolarising response to ACh (the latter is equivalent to the slow excitatory postsynaptic potential, or s-e.p.s.p.). The nature and site of these DA-induced molecular changes, in the unique sequence of events that begins at the ACh-muscarinic receptor and ends with the s-e.p.s.p. response[4], are not yet known, but we may refer to the relevant altered molecular state [A] as the 'product' of process I. Without further processing, [A] would gradually decay over a period of some minutes (certainly less than 30 min), and the responsiveness of the neurone to ACh (or MCh) would revert to the resting control level that existed before the DA modulating action. Cyclic GMP seems to have no effect on process I, or on product [A] and its effectiveness. Process II represents a storage-type of reaction which converts [A], or a separate precursor of [A], into the more durable altered state [B].

experiments similar to those in Figs 1 and 2. The enhancement produced by cyclic AMP could occlude fully the production of any further enhancement by a subsequent dose of DA; and it could also be disrupted by cyclic GMP in a time-dependent manner. It may be argued that the similarity of actions by cyclic AMP and DA is simply due to DA in both cases, with cyclic AMP producing a presynaptic release of DA (a possibility raised by reports for certain other cases[9]). This possibility seems, however, to be excluded here. (1) As noted, the ganglia were almost completely depleted of their functionally-releasable DA by a suitable pretreatment[4,5]. (2) Treatment of a ganglion for 50 min with monobutyryl cyclic AMP (in the presence of theophylline and α-methyl-p-tyrosine) produced no evidence of depletion of functional DA, in contrast to that seen with a briefer bethanechol treatment. The additional important requirement, for a proposal that cyclic AMP mediates the DA-modulatory action, is that DA (or a suitable input of preganglionic nerve impulses) be capable of eliciting an adequate increase in cyclic AMP in the ganglion cells. This requirement has already been met adequately by previous findings[7,8,10].

The scheme presented in Fig. 4 provides a theoretical outline of the full sequence of the physiological actions involved in producing, storing, and 'reading-out' the enduring modulatory effects on the s-e.p.s.p. responses to cholinergic inputs. We do not exclude the possibility that

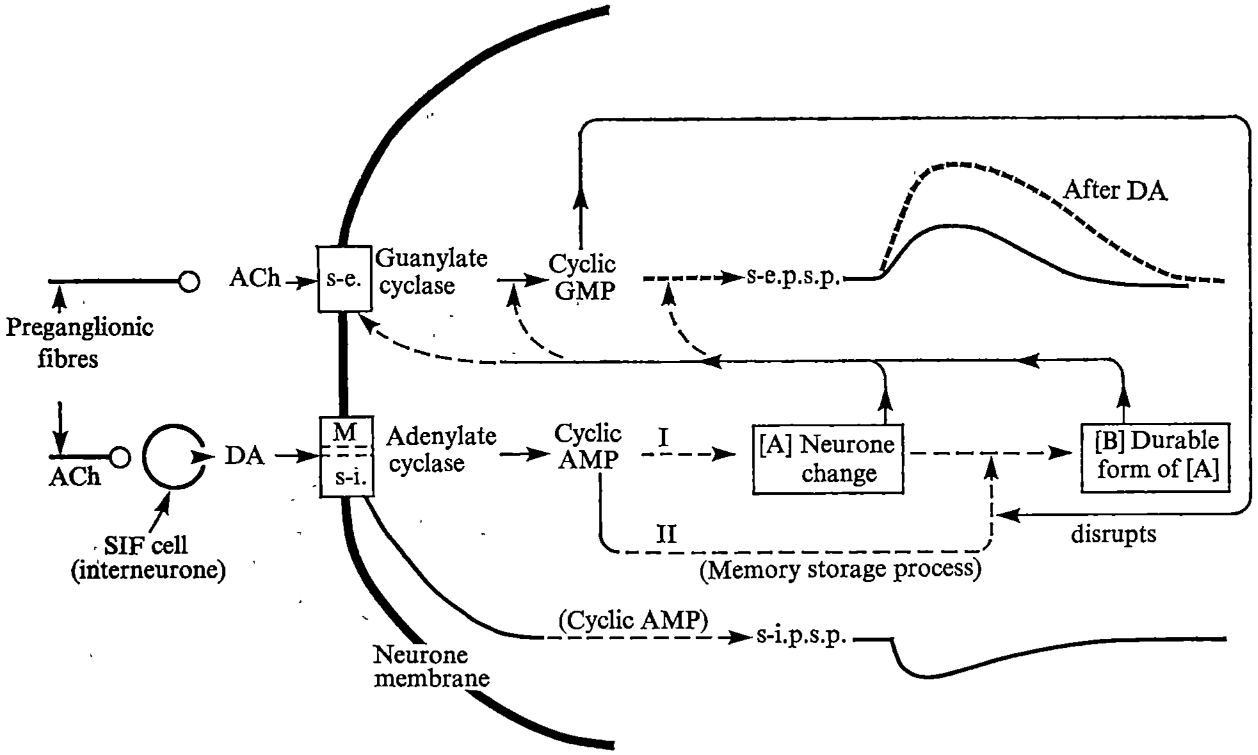

Fig. 4 Schema of pathways for synaptic inputs and intracellular mediators involved in the responses to DA and ACh, for a principal neurone (or ganglion cell) in the rabbit superior cervical ganglion. The s-e.p.s.p. is a slow depolarising change in the membrane potential in response to ACh acting at a muscarinic type of membrane receptor (s-e.); it is represented both before and after (dashed line) its enhancement by a modulatory action of DA. The s-i.p.s p. is a slow hyperpolarising change in membrane potential produced by a direct action of DA. DA is released by a special type of interneurone[5] (the small intensely-fluorescent, SIF, cell as seen with the Falck–Hillarp technique), in response to preganglionic impulses or to an applied muscarinic agonist of ACh[4]. The two postsynaptic actions of DA[1] are designated as M for the modulatory one and s-i. for the hyperpolarising response or s-i.p.s.p.; the actions could be mediated by a single or by two separate membrane receptors. Persisting enhancement of the s-e.p.s.p. response after exposure to DA would be somehow dependent on neuronal change [A] and its more durable form [B]. The question of the precise sites (in the sequence of reactions leading to the s-e.p.s.p. response) at which the modulating neuronal change is operative, is at present being investigated and is represented by a set of dashed arrows. (The proposals for a guanylate cyclase–cyclic GMP role in mediation of s-e.p.s.p. response, and for cyclic AMP as mediator of s-i.p.s p., were made previously[5–8,12].)

cyclic AMP may mediate the direct inhibitory action of DA[6–8], in addition to the enduring modulatory action by DA. On the other hand, the present evidence that cyclic AMP can mediate the DA-modulatory action suggests that this role could be an important one for the DA- (and possibly the noradrenaline-) coupled increases of cyclic AMP in various brain neurones[11].

The DA-modulating action in the sympathetic ganglion provides a model in which the development of a shorter term memory, a memory storage process, and the production and retention of a longer term memory trace, are all accomplished within the same single neurone and are all initially set into motion by the same intracellular messenger (cyclic AMP) following a single brief type of synaptic input. Repetitive synaptic actions fed in by reverberating circuits of nerve cells have been postulated to underlie short term memory and memory storage[2,3], but these are neither necessary nor available in the ganglion. In the present model, a heterosynaptic interaction takes place between two types of synaptic inputs to the same neurone; the memory trace is initiated by a brief (dopaminergic) input in one synaptic line, while the 'read-out' of the memory consists simply in the enhanced ability of the postsynaptic unit to produce its specific response to another (cholinergic) synaptic input. This arrangement provides for a 'learned' change in the response to one input as a result of an 'experience' previously carried by way of another input.

This proposed model does not in itself provide for the specificity of content of a given memory. Some prevalent hypotheses have attempted to provide for such specificity by postulating a specific memory trace[13], but they have suffered from an inadequacy in providing for both the 'read-in' and 'read-out' of the putatively encoded information. Perhaps the specific nature of a given engram could be sought outside the confines of the individual cell in group patternings, but based on the acquisition, by some individual neurones in these groups, of a memory trace that is itself not so specific. The individual neuronal memory portion of such an engram would then acquire a more general character common to many neurones. The view that our proposed model or variants of it may in fact have some general significance receives some support from indirect lines of evidence; the latter have added monoaminergic[14] to the cholinergic pathways already known to widely innervate the forebrain, and have indicated that cholinergic[13] and various monoaminergic transmitters[15] may have roles in long lasting functions of the central nervous system, including those in learning and memory.

Molecular anisotropy of the early *Drosophila* embryo

IT is generally accepted that cellular differentiation depends chiefly on differential gene activity[1]. The model of differential gene activity implies the existence of different inducers/repressors activating/repressing different genes. Indirect evidence for such molecules in *Drosophila* comes from experiments of Illmensee and Mahowald[2] who showed that the information for primordial germ cell determination is in the cytoplasm of the posterior pole of the egg and that when this cytoplasm is transferred to the anterior pole so is the information. Their experiments suggest that genes are regulated not only in time but also in space, possibly by molecules distributed unequally in the developing system[3]. We have analysed *Drosophila* eggs for such molecules.

Kock and Heinig[4] and Nuneman and Moser[5] first approached the problem of unequally distributed molecules in insect eggs by microelectrophoresis and immunoelectrophoresis of parts of the egg of *Achaeta domestica*. They found quantitative differences between the anterior and posterior halves of the egg which probably depend on the unequal distribution of yolk platelets. We have approached this problem in *Drosophila melanogaster* by first developing a technique for producing extracts of different parts of the egg and then producing antisera against these extracts.

Eggs were collected on agar plates seeded with fresh bakers' yeast from population cages containing about 10,000 flies. Eggs (500–700) were oriented vertically on a flat surface with the posterior poles lying in the same plane. When the eggs had reached the desired developmental stage they were frozen in a glass frame. The dimensions of

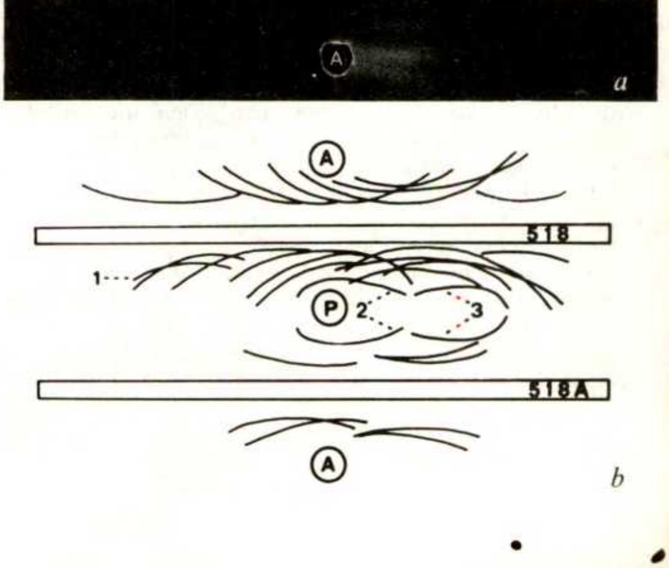

Fig. 1 *a*, Immunoelectrophoresis of 20% posterior (P) and 80% anterior (A) pole extracts. Protein concentration 40 mg ml^{-1}. Bands 1, 2 and 3 were found only in P. Antiserum 518 and antiserum 518A which was absorbed with A. Note that bands 2 and 3 remain unchanged with the absorbed antiserum while other bands either disappear or become weaker. *b*, Tracing of immunoelectrophoresis plate.

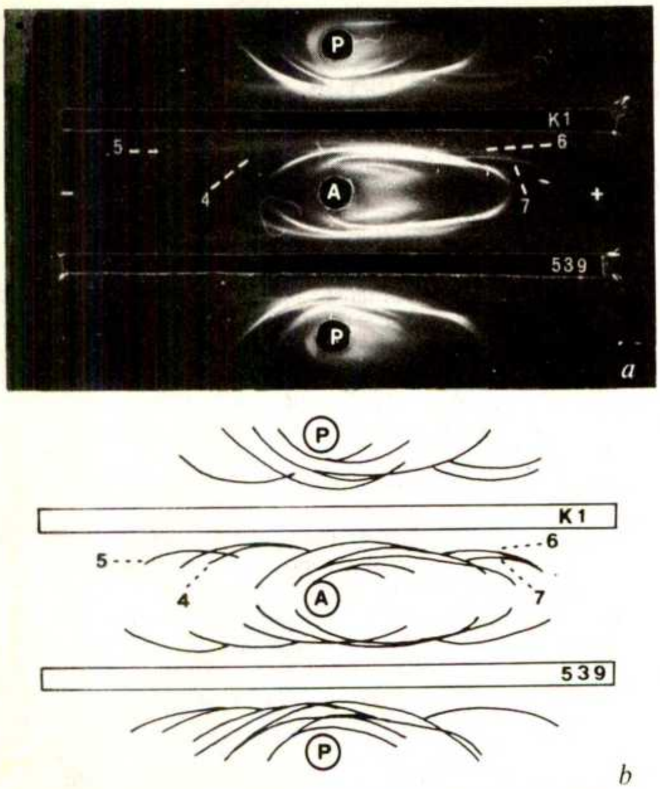

Fig. 2 *a*, Immunoelectrophoresis of 30% anterior (A) and 70% posterior (P) pole extracts. Protein concentration 40 mg ml^{-1}. Band 5 was detected only in A. Bands 4, 6 and 7 show a significant quantitative variation between A and P where they were more concentrated. Antiserum Kl and antiserum 539 also anti-0–4 h embryo. *b*, Tracing of immunoelectrophoresis plate.

the frames were such as to allow different proportions of the eggs to protrude above the surface. The protruding portions of the eggs were cut off in a cryostat microtome and the two parts of the eggs collected in different tubes. By adjusting the dimensions of the frame, the posterior 20%, 30%, 40% and so on, as estimated by the relative protein concentration[6], could be cut off.

The preparation of antisera and other immunological techniques were as reported previously[7]. The extracts were prepared by sonicating the cut embryos. Nine different antisera were used and only three of these showed differences in the antigen patterns of the extracts from different parts of the egg.

Antiserum 518 (0–4-h embryo extract, 30–40% ammonium sulphate fraction) showed antigens present in the posterior pole but not in the anterior pole represented by precipitin arcs 1, 2 and 3 (Fig. 1). These antigens were detected in the posterior 20% of the egg. If larger portions of the posterior part were taken, however, the weaker antigens could not be detected and the stronger ones became weaker, as would be expected if the antigens were located in the extreme posterior cytoplasm and were diluted with anterior cytoplasm lacking them. When the antiserum was absorbed with an extract of the anterior 80% of the egg and used to analyse extracts of the posterior 20%, arcs 2 and 3, identified as being in the posterior part of the egg, were unchanged on immunoelectrophoresis plates while the other arcs disappeared or were reduced because of the removal of the antibodies by absorption (Fig. 1).

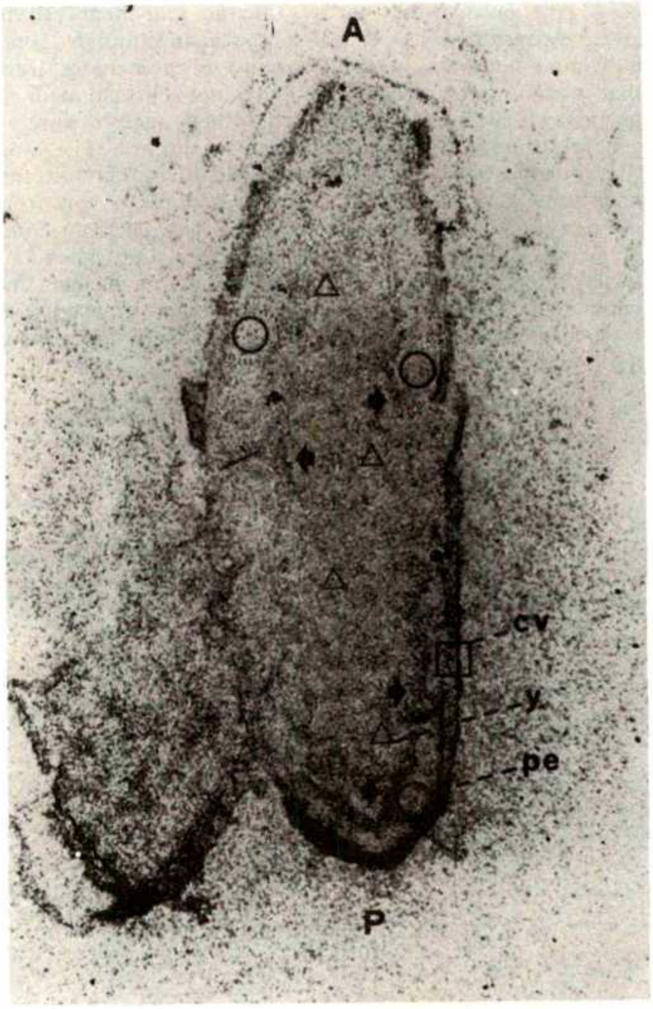
A second antigen showing unequal distribution in the egg was detected with antiserum Kl (0–4-h embryos). Extracts of the anterior 30% and 70% of the egg were compared with extracts of the posterior 70% and 30% respectively. Antigen 5 (Fig. 2) was limited to the anterior 30% of the egg. This antiserum also shows significant quantitative differences.

Antiserum 547 was prepared against an extract of the posterior 30% of the egg and was used to compare extracts of the anterior 30% and 70% of the egg with extracts of the posterior 70% and 30% respectively. One antigen was found in the posterior 30% fraction and not in the anterior 30% or 70% fractions. A second antigen was always associated with the larger portion of the egg irrespective of whether it was the anterior or posterior 70%. We suggest that this antigen is found in the central cytoplasm (including the yolk) and is detected in those extracts with the highest percentage of the cytoplasm, that is, the extracts of the larger part of the egg.

In order to test our proposals that antiserum 547 detected antigens associated with the posterior egg cytoplasm and with the central cytoplasm, as well as more general antigens, we sectioned frozen eggs with a cryostat microtome. The sections were flooded and incubated with antiserum 547, washed with saline and treated with ^{125}I-labelled horse anti-rabbit immunoglobulin. Autoradiographs of the washed slides show most of the radioactivity in the posterior pole of the egg and peripherally in the central cytoplasm at the boundary between the periplasm and the yolk mass thus confirming our prediction of the distribution of antigens detected by this antiserum (Fig. 3).

Although no technique allows us to say that a molecule is not in a certain part of the egg, these results demonstrate

Fig. 3 Autoradiograph of a section of 120-min-old egg treated with antiserum 547 followed, after washing, by treatment with ^{125}I-labelled horse anti-rabbit IgG. Treatment of similar sections with non-immune serum 547 and horse antibody or with horse antibody alone showed only nonspecific association of radioactivity with the chorion and a low overall background. cv, Chorion and vitelline membrane; pe, periplasm; y, yolky cytoplasm; A, anterior pole; P, posterior pole; arrows, boundary line between the periplasm and the yolky cytoplasm.



that some antigens at least are not distributed homogeneously in the egg cytoplasm. This result is all the more interesting as the antigens studied on double diffusion plates must be soluble antigens which *a priori* might be expected to be distributed homogeneously through the cytoplasm Insoluble or membrane bound antigens, the heterogeneous distribution of which might be more readily understood, could only have been detected by the autoradiographic study.

Whether this unequal distribution of antigens in the *Drosophila* egg reflects the mosaic nature of the egg or is a trivial consequence of a more important gradient cannot be decided from these studies. The analysis of mutants showing disturbed embryonic development, for example temperature sensitive female sterile mutants, may help to resolve this problem.

Induction of puffs in *Drosophila* salivary gland cells by mitochondrial factor(s)

IT is well established that specific puffs can be induced in the polytene chromosomes of *Drosophila* larvae by treatments such as heat shock[1–3] and by substances which interfere with respiration[4]; however, the intracellular signals produced in these conditions for the induction of specific puffs are not known. It has been suggested[5] that these signal(s) might come from mitochondria. I have investigated this possibility, using *Drosophila hydei.*

After heat shock a mitochondrial suspension was centrifuged and the supernatant injected into the cytoplasm of salivary gland cells. The responses of chromosomal regions 32A, 36A, 48BC and 81B, which are known to be sensitive to heat shock *in vivo* and *in vitro*[2], were analysed. Table 1 shows the results of analysis of regions 36A and 48BC. Injection of the 'injection medium', followed by 35 min incubation in Poels' medium[6] caused no significant changes in the relative diameters of these two regions. Microinjection into the salivary gland cells of the supernatant from mitochondria which had been subjected to 37 °C caused a significant increase in the relative diameter of regions 36A and 48BC. The extent of increase at region 36A was 11 %, comparable with that obtained from tissue which had been subjected to heat shock *in vitro.* The increase at region 48BC was 23 % over the normal relative diameter of 1.27, a value greater than that (13 %) from heat-shocked salivary glands Even larger puffs can be induced at this chromosome region by vitamin B_6 *in vivo*[7]. Injection of the supernatant from mitochondria which were kept at 20 °C failed to induce puffs at these regions. The puff-inducing ability of the mitochondrial supernatant was greatly reduced after boiling for 10 min. This suggests that the puff-inducing agent(s) require a certain structural configuration to be effective, or that they are complexes which can be dissociated by boiling. These puff-inducing agent(s) seem to have relatively high molecular weight as they could not be dialysed out. The possibility that these mitochondrial agent(s) were nonspecific adhering substances of cytoplasmic origin, being modified and released under heat shock, was also tested. Cytoplasm prepared by lightly homogenising tissue in the 'injection medium' followed by centrifuging at 12,000g to remove cell debris and mitochondria, was heated at 37 °C as described for mitochondria, and injected into intact gland cells At the two concentrations used (about 4 pg and 20 pg protein per cell), no changes were observed in the relative diameters of regions 36A and 48BC.

Figure 1 shows the dose response of the two chromosome regions to the amount of mitochondrial agent(s) injected. The maximum relative diameter of the puff induced at region 36A was attained after injection of about 1.25 pg protein; and at

Third-instar larvae of *D hydei* reared under standardised conditions[8] were used Mitochondria were prepared[9] from 300–400 mg mass isolated[10] salivary glands. The well washed (by repeated suspension and centrifugation) mitochondria, suspended in 0.8 ml of 'injection medium' (0.154 M KCl; 1.0 mM EDTA, *p*H 7 1), were divided into two equal portions. To simulate heat shock, one portion was kept at 37 °C for 35 min, the other portion at 20 °C. After heat shock the mitochondrial suspensions were centrifuged at 27,000g for 100 min at 4 °C. The supernatant is referred to as mitochondrial supernatant. Microinjection was carried out as before[11] The salivary glands, isolated in Poels' medium[6], were submerged in the same solution for microinjection Between eight and 15 cells at the distal end of each gland were injected each with $3–5 \times 10^{-5}$ µl of mitochondrial supernatant, the sister gland was used as control. For the purposes of comparison, the amount of material injected was expressed on a protein basis (2–4 pg per cell) Protein concentration was determined by absorption at 230 nm, thus the absolute amount of protein injected per cell is likely to be overestimated After injection the glands were incubated in Poels' medium[6] at 20 °C for 35 min, then fixed and stained with aceto-orcein; 6–8 injected cells were cut off and squashed The puffing activity of the chromosome regions was expressed as diameter relative to a reference chromosome band which remained inactive under various conditions. *Mean ± s e.m. Figures in parentheses indicate number of cells measured.

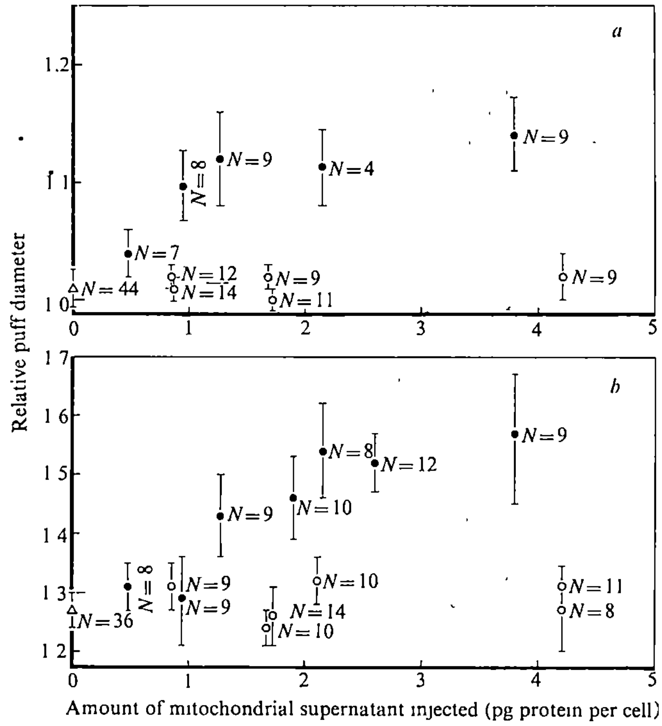

Fig. 1 Response of chromosome regions 36A (*a*) and 48BC (*b*) to injection of various amounts of mitochondrial supernatant from heat treated (●) and control (○) mitochondria. △, Cells injected with injection medium. Vertical bars represent s.e.m. *N*, Number of cells measured.

region 48BC at 2 pg protein per cell. With larger amounts no further substantial increases were observed.

Chromosome region 32A failed to respond to microinjection of the supernatant from the treated mitochondria. Region 81B showed only slight activity and so accurate comparison was not possible. The absence of puff formation at region 32A suggests that the simulation of heat shock of mitochondria *in vitro* does not have the same effect on the mitochondria as it would have in intact tissue, and that more than one puff-inducing agent is required for the induction of all four temperature puffs. The chemical nature of the mitochondrial agent(s) has not been established.

I thank Drs H. J. Leenders, N. Lubsen and I. Sin for their comments.

Rapid loss of a novel phenylalanyl-tRNA on germination of *Neurospora crassa* conidia

SEVERAL theories attempt to explain the control of protein synthesis, and thus development at the level of transfer RNA[1,10]. We present evidence for changes in the isoaccepting species of phenylalanyl-tRNA during germination and growth of the fungus *Neurospora crassa*.

The tRNAs and aminoacyl-tRNA synthetases were isolated from conidia and mycelia as described in the legend of Fig. 1. The conidial tRNA preparation was esterified with ^{3}H-phenylalanine using the conidial synthetase, whereas ^{14}C-phenylalanine was used in the analogous mycelial system. The pattern shown in Fig. 1 was obtained on elution of the tRNAs from a benzoylated DEAE cellulose (BD-cellulose) column. The data were treated according to the method of Shearn and Horowitz[8], thus providing a direct comparison of the tRNA species even though they are labelled with different forms of radioactivity. Mycelial and conidial cultures were shown to contain two and three phenylalanyl-tRNAs, respectively. In addition to monitoring the radioactive amino acids, fluorescence and absorbancy values were also determined. Although the latter two measurements were performed in subsequent experiments, they are presented only in Fig. 1. Fluorescence measurements enable one to distinguish between the cytoplasmic and mitochondrial species of phenylalanyl-tRNA. The cytoplasmic species contain a fluorescent base while mitochondrial species do not (W. E. Barnett, personal communication). Those phenylalanyl-tRNAs which elute late in the salt gradient (fractions 90–100) do not fluoresce and are presumably of mitochondrial origin. The cytoplasm of conidia contains two species of phenylalanyl-tRNA (Phe-tRNA$_{I}^{c}$ and phe-tRNA$_{II}^{c}$), whereas the cytoplasm of mycelia contains only one (Phe-tRNA$_{I}^{m}$).

When the conidia are incubated in a medium which supports germination and growth, the minor species of phenylalanyl-tRNA (Phe-tRNA$_{II}^{c}$) disappears within 3 h. Although tRNAs are normally stable, their rapid loss is not unknown[9].

The levels of methyl-group acceptance are reported[11] to vary in conidial and mycelial populations of tRNA. To test the possibility that the loss of Phe-tRNA$_{II}^{c}$ may result from its conversion by methylation to Phe-tRNA$_{I}^{c}$, the following experiments were performed. Preparations of either conidial or mycelial tRNAs were first esterified with ^{3}H-phenylalanine, then subjected, *in vitro*, to methylation using ^{14}C-S-adenosylmethionine as the methyl donor in the presence of the nuclease competitive inhibitor 2′,3′-cytidine monophosphate (2′,3′-CMP). Control experiments involved incubation of the esterified tRNAs in the methylation reaction mixture minus the methyl donor and 2′,3′-CMP.

Figure 2*a* shows the pattern of methyl-group acceptance in a population of conidial tRNAs. Because the Phe-tRNA$_{II}^{c}$ does not disappear, conversion by methylation is ruled out as a mechanism. Since the levels of the two Phe-tRNA species resolved by the BD-cellulose chromatography were quantified by amino acid charging saturation experiments as well as by fluorescence measurements, the differences in methyl group acceptance between the two forms indicates that Phe-tRNA$_{II}^{c}$ is undermethylated with respect to Phe-tRNA$_{I}^{c}$. Methylation of tRNAs other than Phe-tRNA results in an accumulation of these ^{14}C-labelled compounds in the 0.9 M NaCl wash. When the conidial tRNAs were incubated in the methylase reaction mixture minus the methyl donor and 2′3′-CMP, a measure of endogenous nuclease activity was obtained. As a result of the incubation, Phe-tRNA$_{I}^{c}$ remained at its initial level but the Phe-tRNA$_{II}^{c}$ level was decreased (Fig. 2*b*). Furthermore, some of the ^{3}H-phenylalanine eluted very early in the salt gradient and the remainder was removed in the 20% ethanol wash. The products of the nuclease attack were found in the 20% ethanol wash, whereas the radioactivity which appeared early in the salt wash was free phenylalanine resulting from deacylation of the charged Phe-tRNAs due to the high *p*H of the reaction mixture. Figure 2*c* and *d* is analogous to the experiments described above except that the mycelial tRNA preparation was used. The important features of these latter two experiments are: (1) only a small amount of ^{14}C-methyl label is accepted by the mycelial tRNA^{Phe} suggesting this species is fully methylated *in vivo*; (2) the level of mycelial tRNA^{Phe} is not altered by incubation in the methylase reaction mixture minus the methyl donor and

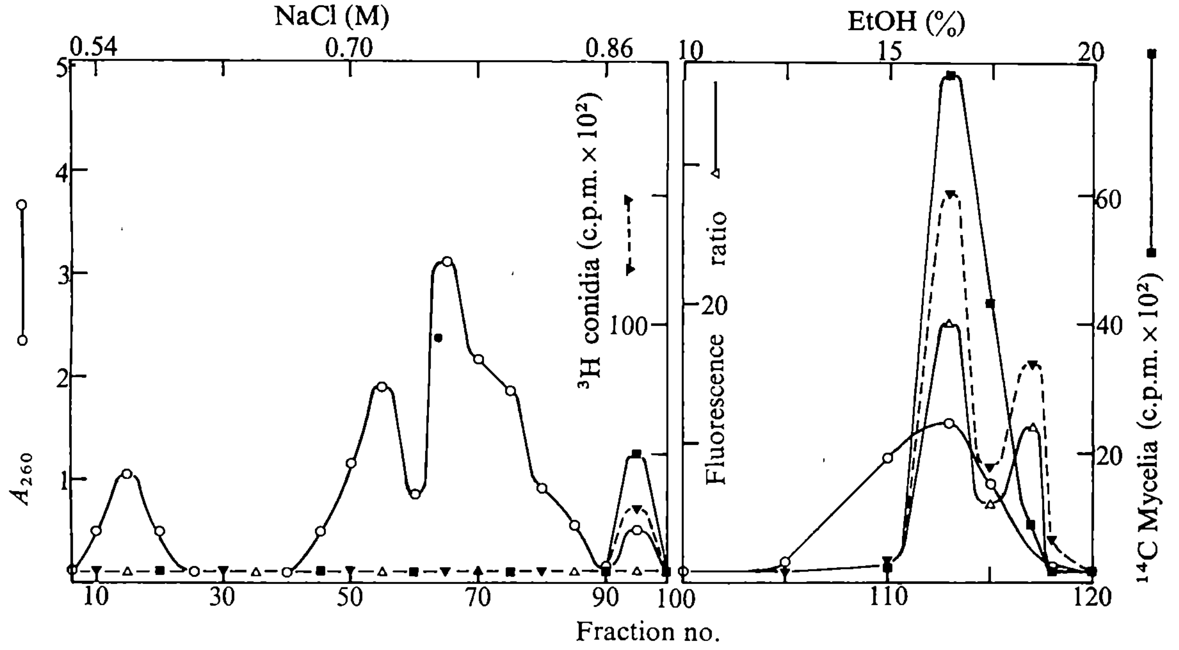

Fig. 1 BD-cellulose column chromatography of phenylalanyl-tRNAs from *N. crassa* conidia and mycelia. Conidia and mycelia, from the wild type strain 74-OR-23-1A, were used as sources of tRNA and aminoacyl-tRNA synthetase. The tRNA was extracted by a modified method of Holley *et al.*[3]. The reaction mixture contained 20 ml of 0.1 M Tris buffer, *p*H 7.4, containing 0.001 M $MgCl_2$ and 0.005 M KCl and 15 ml of water-saturated phenol per 10 g wet weight of cells. The aminoacyl tRNA synthetases were prepared using the method of Haskinson and Khorana[4]. The reaction mixture for the assay of amino acid acceptance was patterned after the methods of Reeves *et al.*[6] and of Shearn and Horowitz[7]. The final concentrations of reactants in the 2.5-ml assay were: Tris-HCl, *p*H 7.5, 50 mM; $MgCl_2$, 15 mM; NaEDTA, 1 mM; Na ATP, 5 mM; ^{14}C or ^{3}H amino acid, 30 µM (specific activity was 50 µCi µmol^{-1} for ^{14}C and 250 µCi µmol^{-1} for ^{3}H); 40–60 A_{260} units of tRNA per ml; and synthetase preparation (2.0 mg ml^{-1}). BD-cellulose column chromatography was carried out as described by Gilliam *et al.*[2] The column was equilibrated with a buffer containing 0.6 M NaCl, 0.01 M $MgSO_4$ and 0.01 M NaAc, *p*H 4.5. The tRNAs were eluted with a 400-ml linear gradient of 0.6 M to 0.9 M NaCl in the above buffer. After completion of the salt gradient, a 200-ml, 10—20% ethanol gradient in the 0.9 M NaCl buffer was applied. Fractions of 4 ml were collected and assayed for radioactivity, absorbance and fluorescence. The fluorescence ratio of 1 ml in 0.1 M K_3PO_4 was measured in a Beckman ratio fluorometer, model 772. The excitation wavelength was 310 nm and fluorescence was measured in the 410–460-nm range.

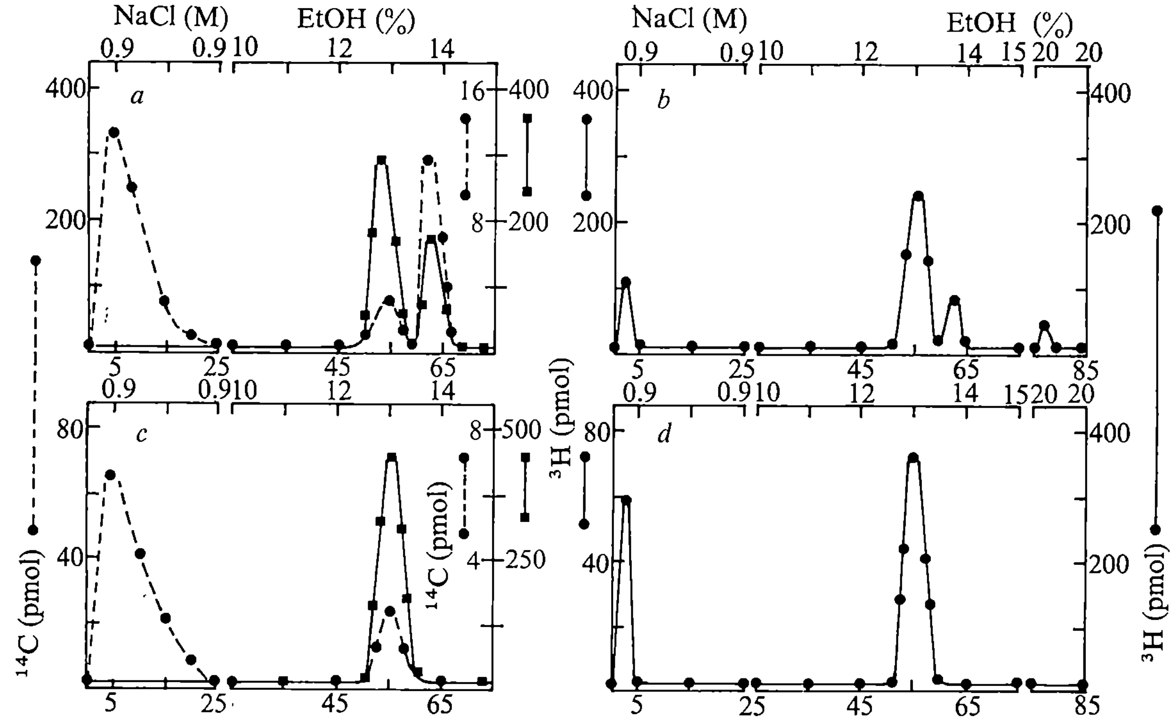

Fig. 2 Effect of methylation on phenylalanyl-tRNA isolated from *N. crassa* conidia and mycelia. The assay for methyl group acceptance by tRNA was patterned after experiments described by Wong *et al.*[11]. The tRNA was esterified and prepared for BD-cellulose chromatography as described in the legend of Fig. 1; however, before application to the column, the tRNA was added to the following reaction mixture: Tris-HCl, *p*H 7.0, 20 µM; mercaptoethanol, 2 µM; $MgCl_2$, 2 µM; tRNA, 100 µg; enzyme, 0.5 mg; ^{14}C-methyl S-adenosylmethionine, 2 µM (specific activity 50 mCi mmol^{-1}). The tRNA preparation was applied to the BD-cellulose column, washed with 0.9 M NaCl buffer, and then eluted with a 10–15% ethanol gradient in 0.9 M NaCl buffer. *a*, Conidial tRNA esterified with ^{3}H-phenylalanine (——); and methylated with ^{14}C (– – – –) in the presence of 1 mM 2′,3′-CMP. *b*, Conidial tRNA esterified with ^{3}H-phenylalanine (——) and incubated in a methylation reaction mixture minus the methyl donor and minus CMP. *c*, Mycelial tRNA esterified with ^{3}H-phenylalanine (——); and methylated with ^{14}C (– – – –), in the presence of 1 mM 2′,3′-CMP. *d*, Mycelial tRNA esterified with ^{3}H-phenylalanine (——); and incubated in methylation reaction mixture minus the methyl donor and minus CMP.

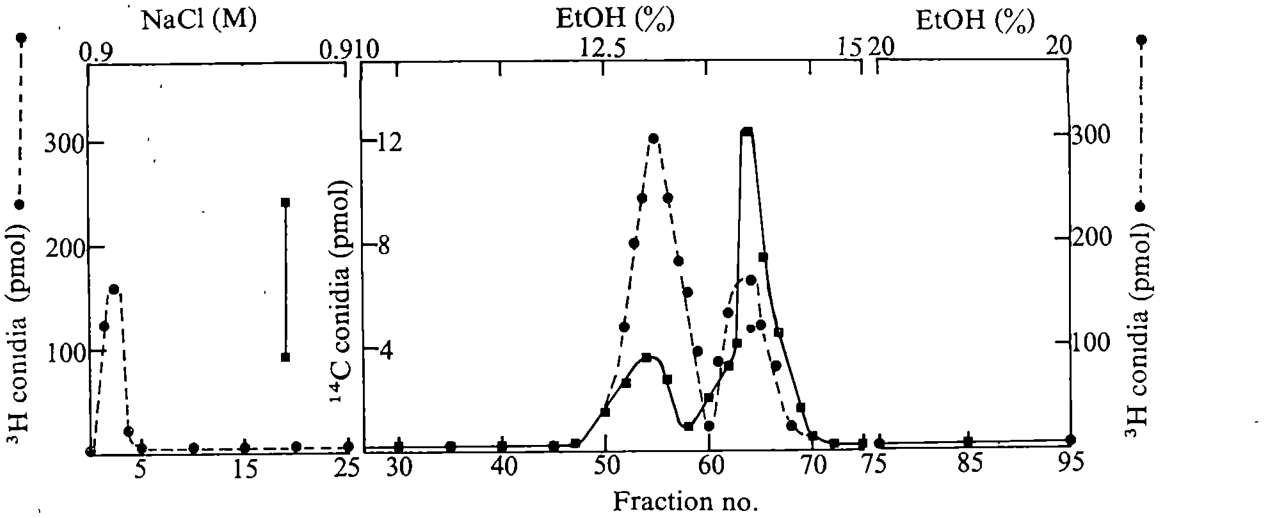

Fig. 3 Protection by methylation of phenylalanyl-tRNA of *N. crassa* from nuclease attack Conidial tRNA^{Phe} esterified with ^{3}H-phenylalanine and then methylated using a ^{14}C-methyl donor (fractions 45–70 from Fig. 2*a*) were reincubated in the methylation reaction mixture but minus the 2′,3′-CMP, then rechromatographed on the BD-cellulose column. – – – –, Phenylalanine-^{3}H, ——, methyl group-^{14}C.

CMP. Since no nuclease products are evident, the free phenylalanine which appears early in the salt wash is due to deacylation rather than nuclease attack of the esterified tRNA^{Phe}.

Although methylation did not convert Phe-tRNA$_{II}{}^c$ to Phe-tRNA$_I{}^c$, *in vitro*, the data from these four experiments indicate that methylation may protect under-methylated species of tRNA from nuclease attack. Whether methylation or 2′,3′-CMP protected Phe-tRNA$_{II}{}^c$ cannot be ascertained from the above experiments. To distinguish between the two possibilities, the following experiment was performed. The tRNAs in fractions 45–70 from Fig. 2*a* were collected, precipitated, and resuspended in the methylation reaction mixture but minus the 2′,3′-CMP. The fractions were rechromatographed and the elution pattern is shown in Fig. 3. The ^{3}H-phenylalanine appeared only as the free amino acid in the early portion of the salt wash and was not associated with nuclease products in the 20% ethanol wash. These data indicate that under-methylated Phe-tRNA$_{II}{}^c$ was protected from nuclease attack by *in vitro* methylation. Thus, the rapid disappearance of Phe-tRNA$_{II}{}^c$ observed *in vivo* may be the result of nuclease action on this labile species of Phe-tRNA.

In an earlier report[5], we showed that phenylalanine exists as a unique NH_2-terminal amino acid in conidia. The transient Phe-tRNA of conidia might function in conidia-specific synthesis of these proteins. If so, a mechanism for its inactivation or destruction on conidial germination would seem to be an essential feature of regulation of this specific protein synthesis. The synthesis or maintenance of levels of glycoprotein associated with amino acid transport in conidia might be related to the transient Phe-tRNA. This glycoprotein is known to have phenylalanine as an NH_2-terminal amino acid (W. D. Stuart, personal communication) and amino acid transport mediated by this permease is known to decrease after germination of conidia. In conclusion, this transient tRNA offers a convenient handle for studying the operation of regulatory mechanisms involved in the transition from the conidial to the vegetative state of *Neurospora*.

We thank Ruth Sadler and Robert R. Schmidt for critical reading of the manuscript and Deborah Minor for help in its preparation. This work was supported by a public service traineeship in genetics from the National Institute of General Medical Sciences.

Deletion of the β-globin structure gene in hereditary persistence of foetal haemoglobin

Hereditary persistence of foetal haemoglobin (HPFH) is a condition characterised by the persistence of a high percentage of foetal haemoglobin into adulthood[1]. The homozygous state has been described in the Negro[2–4] and the Indian[5]; only haemoglobin F is present, and haemoglobins A and A_2 are absent. It has been suggested that in this syndrome γ-chain synthesis fails to switch to β-chain synthesis after birth. The reason for this failure is unknown, although deletions of the β- and δ-structural genes have been proposed[6]. We report here analysis of the DNA from a patient with the homozygous form of HPFH, using radioactive DNAs complementary to β- and γ-globin mRNA (β and γcDNAs); the results are compatible with deletion of the β-globin structural locus.

The annealing of β- and γcDNA to DNA is shown in Fig. 1. The βcDNA annealed to 65% with normal DNA, but only to 35% with HPFH DNA. In contrast, γcDNA annealed equally to normal and HPFH DNA (90%).

In man, from the mode of inheritance of β-globin structural abnormalities, there is believed to be a single β structural locus[8], while structural variation in the γ-globin chains demonstrates that there are two to four γ structural loci[9]. Analysis by DNA hybridisation has confirmed these gene numbers[10]. The smaller extent of hybridisation to the normal DNA of βcDNA compared with γcDNA at the ratio cDNA:DNA used in these experiments is consistent with the larger number of γ-globin genes. The normal rate of hybridisation of γcDNA to both DNAs suggests that the γ-globin genes in HPFH are intact. This agrees with the finding that the foetal haemoglobin of this patient contains both the $^G\gamma$ and the $^A\gamma$ types[9]. The significantly decreased

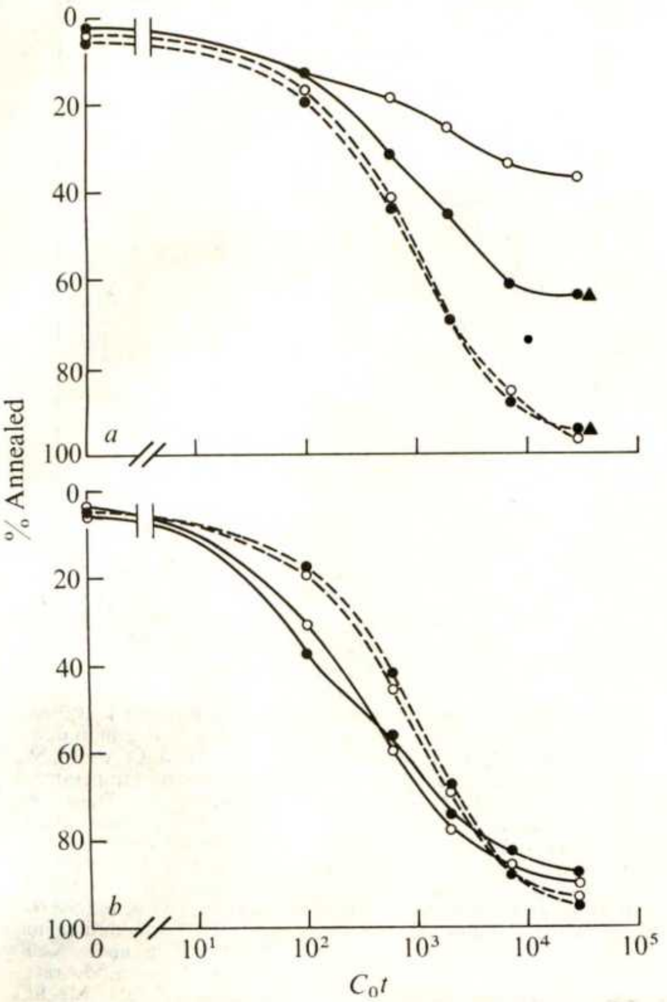

Fig. 1 Rate of annealing of normal and HPFH DNA. DNA was prepared from fibroblasts cultured from a skin biopsy of an HPFH patient, and from the skin fibroblasts and white blood cells (WBC) of two non-thalassaemic controls, as before[7]. βcDNA was transcribed from the 10S RNA (α : β = 1 : 8 by translation) from the reticulocytes of a patient with haemoglobin H disease, and γcDNA was transcribed from the reticulocyte RNA (α : β : γ = 0 : 1 : 8) of a patient with hydrops fetalis. ^{32}P-α-dCTP was used as the label, and the methods for synthesis and isolation of the cDNA were as previously described[7]. Both cDNAs were used without further enrichment of the β or γ sequences. Each 10-μl reaction mixture contained 400 c.p.m. (3.7 pg) of ^{32}P-labelled β or γcDNA, 75 μg of cellular DNA, 500 c.p.m. of ^{3}H-dCTP labelled HeLa unique sequence DNA as internal controls, 0.5 M NaCl, 0.04 M Tris-HCl (*p*H 7.4) and 1.5 mM EDTA, and was incubated for 0–72 h at 68 °C. Hybrids were assayed with hydroxylapatite[7]. *a*, βcDNA; *b*, γcDNA. ●, Normal WBC DNA; ○, HPFH fibroblast DNA; —, cDNA; - - -, unique sequence Hela DNA; ▲, shows that the annealing of βcDNA to normal skin fibroblast DNAs was identical to the WBC DNA.

hybridisation of βcDNA in HPFH is compatible with the deletion of all or part of the single β locus. There are several possible reasons why some βcDNA annealed to the HPFH DNA. First, 10–15% can be attributed to the α sequence known to be present in the βcDNA, Second, some portion of the β-structural gene may remain undeleted. Third, nonspecific αcDNA hybrids with low thermal stability have been found in hydrops fetalis where the α-globin structural genes are deleted (ref. 7 and unpublished work of Y.W.K.). Similar nonspecific hybridisation of the βcDNA may occur in the absence of β-globin structural genes.

We cannot infer from these data whether or not the δ-globin gene is affected, as the extent of cross hybridisation between β and δ sequences is not known. The absence of haemoglobin A_2 in homozygous HPFH suggests involvement of the δ-globin gene also, but this may not necessarily be due to deletion, as other mechanisms resulting in the absence of δ-chain synthesis may be possible.

In conclusion, the decreased hybridisation of the βcDNA to HPFH DNA indicates that all or a large portion of the β-globin locus is deleted in this syndrome.

Effect of DTNB light chain on the interaction of vertebrate skeletal myosin with actin

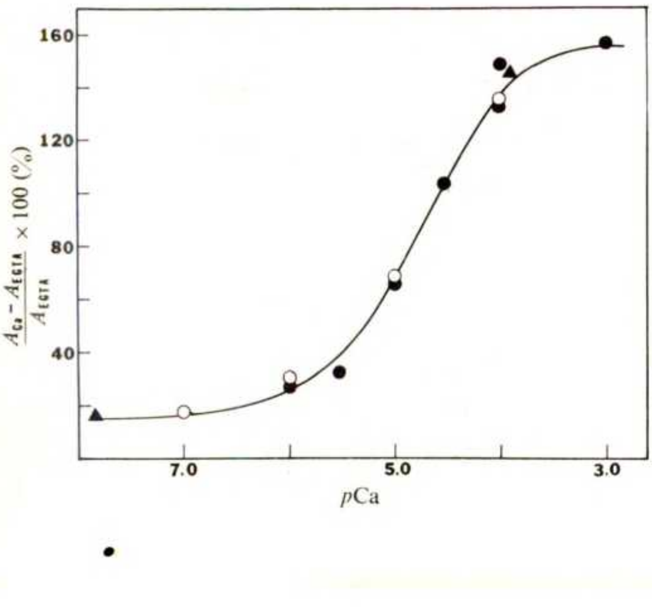
MYOSIN from vertebrate skeletal muscles contains four low molecular weight subunits which are thought to play a functional role in the enzymic activity of myosin[1,2] Removal of 'alkali light chains' (21,000 and 17,000 g mol^{-1}) results in complete loss of ATPase activity, but dissociation of 'DTNB light chain' (18,000 g mol^{-1}) leaves the enzymic activity of myosin essentially unaffected[3–6]. Since harsh solvents are required to dissociate alkali light chains from heavy chains (as the name implies), it is unclear whether the activity loss is related primarily to denaturation of the heavy chain or to removal of the light chain[7].

The only light chain for which a function has been clearly defined is that associated with myosin from molluscan muscles. It is now well documented that calcium regulation in molluscs is through the thick filament; the thin filaments lack troponin and do not bind calcium[8]. Thus the 'EDTA light chain' of scallop myosin is a true regulatory subunit in that it controls whether the muscle is in an active or a resting state[9]. No comparable calcium sensitivity has been shown for vertebrate skeletal myosin, although rabbit myosin[10], as well as isolated DTNB light chains[11], can bind calcium in the 10^{-5} M range. Nevertheless, some effects of calcium on the properties of myosin filaments have been observed. The sedimentation coefficient of isolated, native thick filaments increases by about 3% with increasing calcium levels[11]. X-ray diffraction patterns from contracting muscle indicate a movement of cross bridges on activation, which is independent of the presence of actin[12]. Both studies suggest a conformational change occurring within the thick filament. The biological significance of these observations however, is unclear; and an involvement of the DTNB light chain in these structural changes has not been unequivocally demonstrated. We present here data showing that the DTNB light chain is directly involved in the interaction between myosin and actin, and moreover, that the strength of this interaction depends on the concentration of calcium present in the medium.

At some stage in the contractile cycle, myosin is probably bound to actin in a 'rigor'-type linkage. The energy needed to break this bond is derived from the binding of ATP to myosin. A value for the association of myosin and actin in the absence of ATP has been estimated to be no less than 10^6 M^{-1} and may be considerably higher[13,14]. We have redetermined this parameter by analysing the binding of heavy meromyosin (HMM) and heavy meromyosin subfragment 1 (S1) to F actin in the analytical ultracentrifuge, using the scanning absorption optical system at 230 nm. By adding an increasing concentration of enzyme to a fixed amount of F actin and sedimenting the complex, the free concentration of enzyme can be measured in the supernatant and a binding isotherm constructed. The details of these experiments will be presented elsewhere, but the principal conclusions may be summarised as follows: the association constant for HMM and actin is 1×10^6–4×10^6 M^{-1} in 0.1 M KCl, 10 mM imidazole, *p*H 7.0, 1 mM $MgCl_2$, 5 mM Pi; the corresponding value for S1 is about 10^5 M^{-1}. Unexpectedly, we found that these values increased nearly tenfold on addition of 0.3 mM EGTA to the basic solvent, whereas 0.1 mM Ca^{2+} caused a significant reduction in binding[15]. Figure 1 shows that the midpoint of this transition in binding occurs at about *p*Ca 5. Although this amount of calcium is an order of magnitude higher than that required to activate skeletal muscles, it is still well within the physiological range of calcium reached in a contracting muscle cell.

Having shown a calcium response in vertebrate skeletal myosin, the question arises as to the site of calcium action. Since calcium affects the interaction with actin, an involvement of the head region of myosin is indicated; and, indeed, both HMM and S1 are sensitive to calcium. The magnitude of the response, however, varied from one preparation to the next, suggesting possible proteolytic degradation of essential sites. This variation was most pronounced for S1, where some preparations gave less than 20% of the effect observed with myosin.

Fig. 1 Effect of calcium concentration on the extent of actomyosin formation. Rabbit myosin (1.27 mg ml^{-1}) was mixed with F actin (0.24 mg ml^{-1}) in 0.34 M KCl, 10 mM imidazole (*p*H 7.5), 5 mM KPi and 1 mM $MgCl_2$ in a volume of 2 ml. The calcium level was adjusted by Ca-EGTA–EGTA buffers. The reaction mixture was stirred for 30 min in the cold, before centrifugation at 40,000 r.p.m. in the analytical ultracentrifuge. The concentration of unbound myosin in the supernatant was determined at 280 nm with the photoelectric scanner (Model E). Each point represents the difference between the absorbance (A_{Ca}) in the presence of calcium and in its absence (A_{EGTA}), relative to the absorbance in 0.3 mM EGTA. *p*Ca is the negative logarithm of the molar concentration of free calcium. Five measurements could be made simultaneously using the AN-G rotor with the multiplexer accessory. ○, ●, ▲, Different preparations.



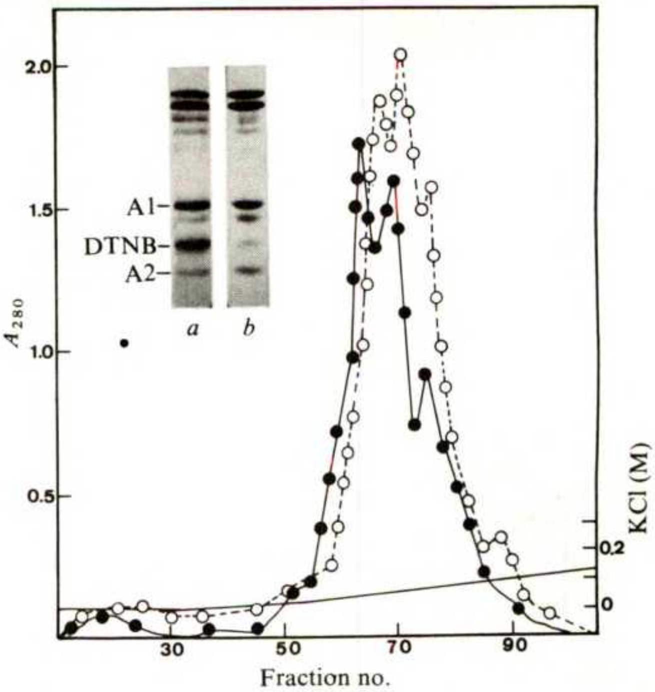


Fig. 2 Chromatographic purification of subfragment 1. Rabbit myosin at about 2% was dialysed against 0.2 M ammonium acetate, *p*H 7.2, in the presence of either 2 mM $MgCl_2$ or 2 mM EDTA. The precipitated myosin was digested at room temperature for 7 min with 0.03 mg ml^{-1} papain (Worthington). Digestion was stopped by adding iodoacetic acid to a final concentration of 1.0 mM. Insoluble material was removed by centrifugation and the supernatant dialysed against 0.05 M Tris-HCl (*p*H 7.9), 0.5 mM dithiothreitol, containing either 2 mM $MgCl_2$ or 2 mM EDTA. About 450 mg subfragment 1 was applied to a 2.5×60 cm DEAE-cellulose column (Whatman DE52) equilibrated in the same buffer. The protein was eluted with a linear KCl gradient (0.0–0.5 M KCl in a total volume of 2 l) at a flow rate of 45 ml h^{-1}, collecting 6 ml per tube. Fractions 60–70 of Mg–S1 (●) and 60–72 of EDTA–S1 (○) were pooled and the material salting out between 49 and 58% saturated ammonium sulphate retained for further experiments. Representative samples of Mg–S1 (*a*) and EDTA–S1 (*b*) at 15-μg loads on 10% SDS–polyacrylamide gels are shown above.

The standard procedure for preparing S1, the 'single head' of myosin, is to digest a suspension of myosin with a low concentration of papain[14]. S1 prepared in this manner shows one symmetrical peak in the ultracentrifuge, has a high level of ATPase activity, and is regulated by the troponin–tropomyosin system. Gel electrophoresis of rabbit S1 gives two bands of about 90,000 and three light chain components plus an extra band (which probably originates from cleavage of the heavy chain)[16] in the 20,000 g mol^{-1} region. Densitometry of such gel patterns shows that less DTNB light chain is present in S1 than occurs per head of native myosin, a finding consistent with radiochemical studies indicating a loss of ~0.5 mol DTNB light chain per mol S1 (ref. 3).

The susceptibility of DTNB light chain to proteolysis is reminiscent of the early difficulties in preparing S1 from scallop myosin[9]. Depending on whether divalent cations were present or absent in the digestion medium, EDTA light chain remained intact or was completely degraded by papain. These results suggested that perhaps the stability of DTNB light chain might be similarly affected by the presence of magnesium ions. Consequently the procedure for digesting rabbit myosin to S1 was modified to include 2 mM $MgCl_2$ or 2 mM EDTA in all solutions (see legend to

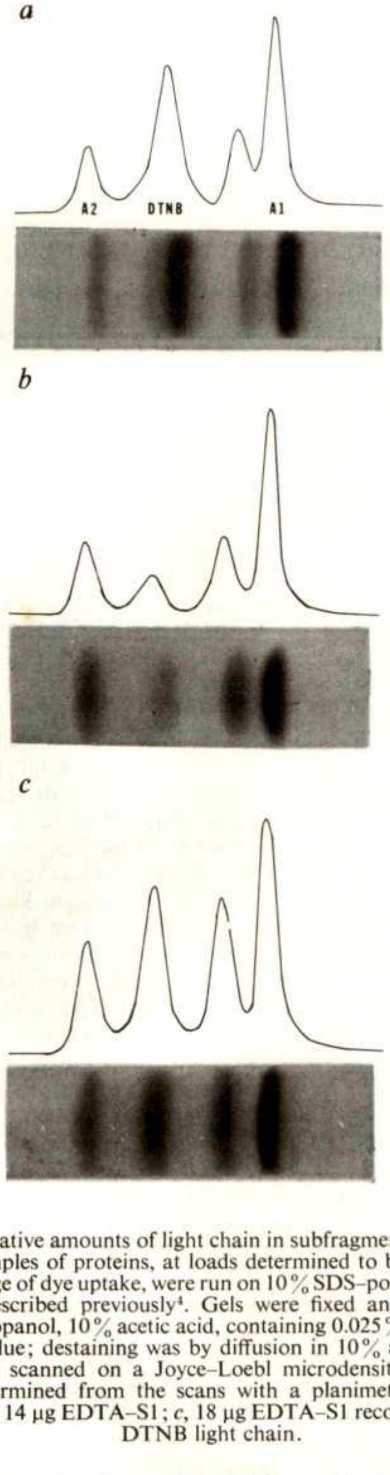

Fig. 3 Relative amounts of light chain in subfragment 1 preparations. Samples of proteins, at loads determined to be within the linear range of dye uptake, were run on 10% SDS–polyacrylamide gels as described previously[4]. Gels were fixed and stained in 25% 2-propanol, 10% acetic acid, containing 0.025% Coomassie brilliant blue; destaining was by diffusion in 10% acetic acid[18]. Gels were scanned on a Joyce–Loebl microdensitometer, and areas determined from the scans with a planimeter. *a*, 14 µg Mg–S1; *b*, 14 µg EDTA–S1; *c*, 18 µg EDTA–S1 recombined with DTNB light chain.

Fig. 2 for details). Chromatographic profiles of Mg-S1 and EDTA-S1 are illustrated in Fig. 2, together with electrophoretic patterns of the pooled fractions. These gels provide clear evidence that S1 prepared in the presence of magnesium ions has a significantly higher proportion of DTNB light chain than S1 digested in EDTA. In fact, densitometry of the chromatographed samples showed that Mg-S1 has approximately the same content of DTNB light chain as myosin (Fig. 3 and Table 1). The relative amount of alkali 1 to alkali 2 was fairly constant in both types of subfragment, and gave a ratio similar to that found for native rabbit myosin[17].

A preliminary characterisation of Mg-S1 and EDTA-S1 revealed few major differences in their properties: Both appeared monodisperse in the ultracentrifuge and sedimented at about equal rates, although inspection of the shape of the sedimentation velocity profile suggested a possible difference in frictional coefficients. The Ca^{2+}- and EDTA-activated ATPases for the two proteins were in the range of 3 and 10 s^{-1}, respectively; and the actin-activated ATPase was between 13 and 16 s^{-1}. The activity of both preparations was inhibited by troponin–tropomyosin to the extent of 70–80% in the absence of calcium. These results confirm previous reports that DTNB light chain is not involved in actin-linked regulation[18].

The most significant difference between the preparations of Mg-S1 and EDTA-S1 was in their response to calcium,

Table 1 Relative amounts of light chain in subfragment 1

Subfragment	Experiment	Alkali 1	DTNB light chain	Alkali 2
EDTA-S1	1	1.15	0.29	0.85
	2	1.29	0.36	0.71
	3	1.14	0.48	0.86
Mg-S1	1	1.28	1.79	0.72
	2	1.21	1.71	0.79
	3	1.71	2.00	0.29
Recombined	1	1.23	0.66	0.77
	2	1.20	1.12	0.80
	3	1.03	0.81	0.97

Amount of each light chain relative to the total light chain content was determined by dividing the densitometer area by the molecular weight and normalising values to mol (A1+A2 = 2). Each value represents an average of 4–6 determinations. Conditions for electrophoresis were as in Fig. 3. "Recombined" subfragment was prepared by adding total light chains (300 mg) or purified DTNB light chain[18] (80 mg) to EDTA-S1 (300 mg), and separating the subfragment from the uncombined light chains by ion-exchange chromatography as in Fig. 2.

Fig. 4 Ultracentrifuge scanner traces of the binding of subfragment 1 to F actin as a function of calcium. Mg–S1 (0.33 mg ml^{-1}) or EDTA–S1 (0.33 mg ml^{-1}) in 0.10 M KCl, 10 mM imidazole (*p*H 7.0), 5 mM KPi, 1 mM $MgCl_2$, containing either 0.1 mM $CaCl_2$ or 0.3 mM EGTA, was added to F actin (0.24 mg ml^{-1}) in a final volume of 2 ml. The mixture was stirred for 30 min before centrifugation at 40,000 r.p.m. The concentration of free enzyme remaining in the supernatant was determined at 230 nm from the magnitude of the plateau region, and corrected for unpolymerised actin. *a* and *b*, Mg–S1 in the presence and absence of calcium, respectively. *c*, EDTA–S1; scan was the same for calcium or EGTA.

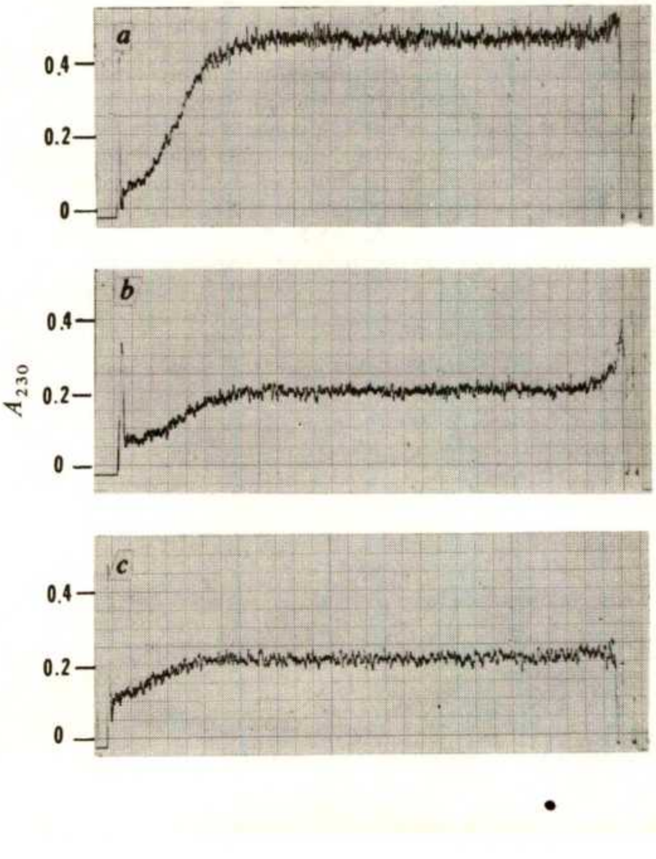

Table 2 Effect of calcium on binding of subfragment 1 to actin

Subfragment	Experiment	A_{230} 0.1 mM $CaCl_2$	 0.3 mM EGTA	Calcium sensitivity (%)
EDTA–S1	1	0.28	0.28	—
	2	0.37	0.36	—
	3	0.24	0.24	—
Mg–S1	1	0.76	0.31	147
	2	0.78	0.32	148
	3	0.46	0.20	130
Recombined	1	0.56	0.28	100
	2	0.58	0.31	87
	3	0.45	0.32	41

Absorbances for subfragments were obtained as in Fig. 4. "Calcium sensitivity" is expressed as $((A_{Ca}-A_{EGTA})/A_{EGTA})\times 100$.

using the binding of S1 to actin as an assay. Figure 4 shows that when Mg-S1 was reacted with actin in the presence of calcium, twice as much enzyme remained unbound in the supernatant as when a chelating agent was present. In contrast, the amount of free EDTA-S1 remained invariant with calcium concentration. Several such experiments are summarised in Table 2. Although the difference in DTNB light chain content is the most striking feature of the S1 preparations, it must be recognised that minor modifications in the heavy chain could be responsible for the unresponsiveness of EDTA-S1 to calcium. It was therefore important to demonstrate that addition of DTNB light chain to EDTA-S1 would restore the calcium effect. Preliminary efforts at recombination are shown in Tables 1 and 2 and Fig. 3. In spite of difficulties in achieving full recombination of DTNB light chain, the results do indicate a partial restoration of the calcium response.

The experiments reported here demonstrate that the DTNB light chain is directly involved in the binding of calcium to vertebrate skeletal myosin. These findings should not be interpreted to mean that a second control mechanism necessarily exists in vertebrate muscles. The effect of calcium observed here is to weaken rather than to strengthen the actomyosin interaction. Furthermore, the level of calcium required for this effect is considerably higher than that needed to activate muscle. Nevertheless, the results show that the properties of the myosin head can be affected by the DTNB light chain, and perhaps it is not too unrealistic to speculate that subunit interactions of this kind may have an important role in the attachment of a cross bridge to actin during the contractile cycle.

Fluorescence lifetimes in the photosynthetic unit

THE fluorescence intensity of a photosynthetic organism at any instant is a measure of the concentration of excited chlorophyll and it has, therefore, been one of the most studied of all the phenomena related to photosynthesis. Fluorescence lifetimes are a direct measure of the rate of energy transfer from the light collecting unit to the chemical trap. Lifetimes in the nanosecond region have been measured by many workers, following the pioneering work of Brody and Rabinowitch[1], but these have been near the limit of time resolution of the apparatus used. Much shorter average lifetimes have been measured by phase shift methods[2]. The picosecond pulses which are available from mode-locked lasers have now made possible a fully time-resolved study of fluorescence decay in the photosynthetic units of algal chloroplasts and their fragments.

The first laser pulse measurements on picosecond fluorescence lifetimes used the electro-optical shutter[3–5] but the irreproducibility of pulse intensity makes this a rather imprecise method. The streak camera[6,7] has greatly improved the precision but much of this is lost if photographic recording is used. With silicon-target, vidicon multichannel detection, which we have used in this work, the streak camera provides the best precision available at present for picosecond fluorescent kinetic studies. The picosecond pulses were generated from a mode-locked Nd^{3+} glass oscillator and the second harmonic at 530 nm was produced with 10–15% efficiency by a temperature-tuned caesium dihydrogen arsenate crystal. The train of pulses (approximately 100 with pulse separation of 6.7 ns) was directed at 45° on to the front surface of a cuvette (1 mm thick) containing the sample. The fluorescence passed through a Barr and Stroud DB5 CYAN filter to the slit of an Imacon streak camera which had an S20 photocathode. The fluorescence from one pulse near the centre of the train was selected for examination; this pulse had a duration 5–10 ps and its energy was typically 200 μJ. The signal was recorded on a 500-channel optical multichannel analyser and was calibrated both in intensity and in time.

Fluorescence lifetimes of algae, chloroplasts and chloroplast fragments have been measured. The algae used were *Chlorella pyrenoidosa* and *Porphyridium cruentum* grown in liquid culture[8] and collected during the logarithmic growth phase. Chloroplasts were isolated from spinach leaves (*Spinacea oleracea*) by a method previously reported[9] except they were subjected to osmotic shock before being suspended in the experimental medium which consisted of 0.33 M Sorbitol, 1 mM $MgCl_2$, 1 mM $MnCl_2$, 2 mM EDTA and 50 mM HEPES brought to *p*H 7.6 with KOH. Subchloroplast particles were prepared by the method of Anderson and Boardman[10]. Measurements with algae were made with 10–15% suspensions, and with chloroplasts and subchloroplast particles the chlorophyll, as determined by Arnon's method[11], was about 3 mg ml^{-1}. Fluorescence emission and yields were also measured in the nanosecond region of the decay using a conventional single-photon counting system.

Figure 1 shows the fluorescence decay curves for the two algae and Fig. 2 shows the decays for untreated spinach chloroplasts and for the same chloroplasts treated with 20 mM sodium dithionite, which reduces the activity of the chemical traps. The decays of *Chlorella*, *Porphyridium* and untreated chloroplasts were exponential from 20 to 300 ps after excitation and their decay times are given in Table 1. Beyond 300 ps there

Table 1 Fluorescence lifetimes of algae and chloroplasts

	τ (ps)
Chlorella	108 ± 10
Porphyridium	92 ± 10
Chloroplasts	134 ± 10
Chloroplasts + dithionite	130 ± 20 $1,450 \pm 150$

is evidence of a very weak longer lived component of the fluorescence.

Dithionite treatment of chloroplasts had little effect on the main component of fluorescence but markedly increased the intensity and lifetime of the longer lived component and the total yield of fluorescence. The longer lived component was measured on our nanosecond single-photon counting apparatus (1.6 ns) as well as on the picosecond apparatus (1.45 ns) and the decay was exponential. These lifetimes agree with previous measurements in this region[12].

Sub-chloroplast particles centrifuged at 1,000, 10,000, 50,000 and 144,000*g* gave increasing intensity of the shorter lived component over that of the longer lived one. This is probably to be attributed to the higher proportion of photosystem I (PS I) in the high *g* centrifuged particles. This, together with the effect of dithionite on the longer lived component of the chloroplast, suggests that the shorter and longer decays are to be identified with PS I and PS II respectively.

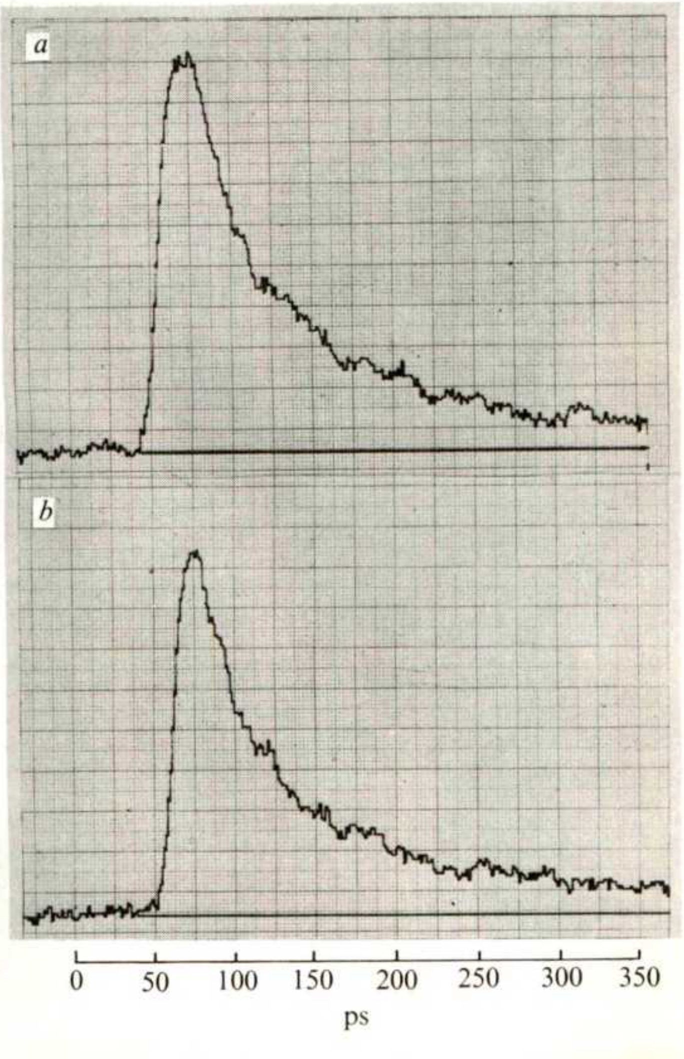
In the chloroplasts treated with dithionite, the two fluorescence decays (attributed to PS I and PS II) are quite distinct and it has been possible to make quantitative measurements on their relative contributions to the fluorescence. The relative numbers, *f*, of chlorophyll *a* molecules initially excited in the two systems is given directly by the ratio of initial fluorescence intensities of the two components, which is 4.5, the shortest component being the more intense. From this, and the measured lifetimes, the fluorescence yield of each system may be calculated from the relationships:

$$\varphi_{\rm I} = f_{\rm I}(\tau_{\rm I}/\tau_0)$$

$$\varphi_{\rm II} = f_{\rm II}(\tau_{\rm II}/\tau_0)$$

where $\varphi_{\rm I}$, $\tau_{\rm I}$ and $f_{\rm I}$ are the fluorescence yield, the lifetime and the fraction of excitation transmitted to chlorophyll *a* molecules of

Fig. 1 Fluorescence decay of intact algae. *a*, *Porphyridium cruentum*; *b*, *Chlorella pyrenoidosa*.



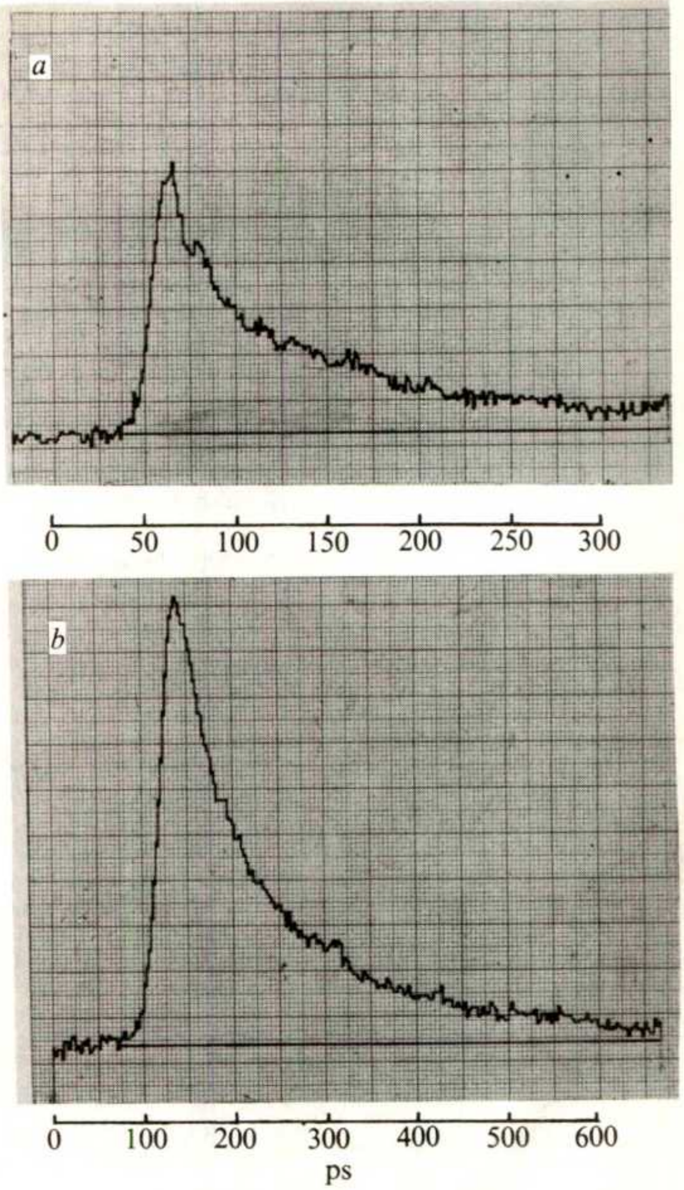


Fig. 2 Fluorescence decay of chloroplasts. *a*, Spinach chloroplast; *b*, spinach chloroplast and dithionite.

Table 2 Fluorescence yields of dithionite-treated chloroplasts

	τ (ps)	*f*	φ (calculated)		(measured) φ
PS I	130	0.82	0.0056	0.020	0.024
PS II	1,450	0.18	0.014		

photosystem I, and subscript II refers to the same quantities for system II; τ_0 is 19 ns, the natural lifetime of chlorophyll *a* (ref. 13). It will be seen from Table 2 that the calculated yield of total fluorescence agrees well with our direct measurements for the same chloroplasts.

It should be noted that the ratio, *f*, of 4.5, determined from the initial fluorescence intensities of the two decays, involves the accessory pigment absorption and measures the ratio of chlorophyll molecules excited in each system rather than the ratio of unexcited chlorophyll molecules. It refers to the excitation wavelength of 530 nm. The ratio is higher than has been predicted from measurements of the quantum yield of photosynthesis at this wavelength[14,15] and casts doubt on the feasibility of distinguishing photosystems I and II on the basis of their lifetimes.

Kollman, Shapiro and Campillo[7] have attributed the short lifetimes of chlorophyll fluorescence *in vivo* to concentration quenching, on the grounds that similar lifetimes are found in concentrated solutions of chlorophyll. Such an interpretation would be inconsistent with the operation of efficient photosynthesis and, although concentration quenching, probably of a special type which we discuss elsewhere, accounts for the lifetimes of fluorescence in concentrated solutions of chlorophyll *in vitro*, it cannot be important in an efficient photosynthetic system. We have considered one other possible cause of quenching of excited chlorophyll molecules in the *in vivo* measurements reported here—the intensity during measurement is so high that a significant fraction of the chlorophyll molecules is excited. Singlet-singlet annihilation could become important in these conditions, and possibly singlet–triplet annihilation involving triplets formed in earlier pulses. We therefore carried out the measurements on porphyridium over a tenfold range of intensities; the decay rates of fluorescence were unaffected by the intensity change and we conclude that exciton interactions are unimportant in the conditions of our experiments. In some cases, the initial rate, immediately after the flash, was somewhat faster than that reported in Table 1 but this would be expected from the time-dependent term in the theory of excitation diffusion (see ref. 16).

The lifetimes we have recorded are a direct measure of the average time taken for an absorbed photon to be trapped at the reaction centre in the conditions of our experiments.

Fragmentation of benzylpenicillin after interaction with the exocellular DD-carboxypeptidase-transpeptidases of *Streptomyces* R61 and R39

THE killing target of penicillin in bacteria is a membrane-bound transpeptidase which catalyses peptide cross linking during wall peptidoglycan synthesis[1,2]. *Streptomyces* R61 and R39 excrete during growth DD-carboxypeptidase-transpeptidase enzymes[3,4] which seem to be soluble forms of the corresponding membrane-bound transpeptidases[5]. The exocellular enzymes (E) convert penicillin (I) in to a chemically altered and biologically inactive compound (X)[6,7]. Kinetically, the simplest mechanism[5] for the conversion of I into X is

$$E + I \overset{K}{\rightleftharpoons} EI \xrightarrow{k_3} EI^* \xrightarrow{k_4} E + X$$

The first step, a rapid equilibrium process, leads to the formation of an equimolar and inactive enzyme–antibiotic complex EI. This complex isomerises into a modified complex EI* which, in turn, undergoes irreversible breakdown. If the experiment is carried out in conditions in which the enzyme is stable, the enzyme is reactivated and recovers its initial penicillin sensitivity. The breakdown of complex EI* is a slow process. At 37 °C and in 10 mM Na phosphate buffer, *p*H 7.0 (in which conditions the R61 enzyme is stable) the half life of the R61 enzyme–benzylpenicillin EI* complex is 80 min (ref. 7). At 37 °C and in 0.1 M Tris-HCl buffer, *p*H 7.7, containing 0.1 M NaCl and 0.05 M $MgCl_2$ (in which conditions the R39 enzyme is stable), the half life of the R39 enzyme–benzylpenicillin is 4,250 min (ref. 6). As the enzyme is reactivated during the process, no enzyme is irretrievably lost on reaction with penicillin and after several cycles of inactivation and reactivation, both the enzyme and the accumulated X

Fig. 1 Mass spectra of authentic phenylacetylglycine (*A*, molecular weight = 193) and X compound (*B*). ^{14}C-X (0.5 μeq) was dissolved in 100 μl of 6 N HCl and extracted, at room temperature, with 300 μl of ethyl acetate (yield of the extraction 60% in terms of d.p.m.). Mass spectrography was carried out on a sample of the extract containing 5 neq of ^{14}C-X and compared with that given by 1 μg of phenylacetylglycine. Spectra were recorded at 70 eV with an ionisation current of 60 μA. The sample was directly introduced (193 : molecular ion M^+).

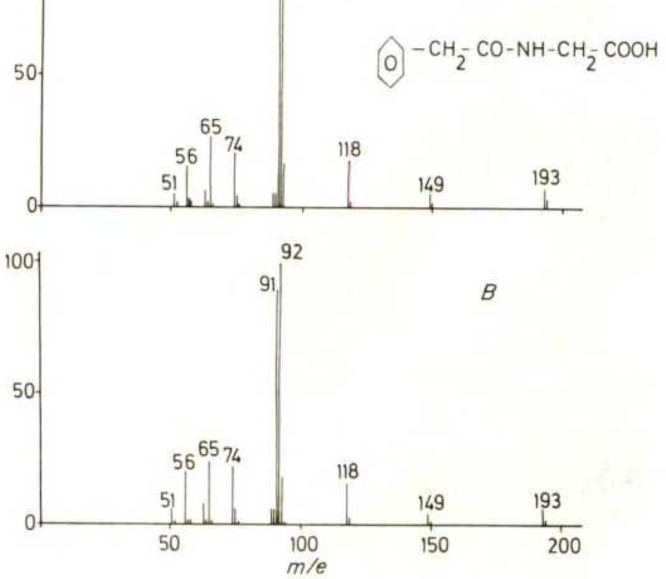

Table 1 R_f values of ^{14}C-X and phenylacetylglycine and of HCl-hydrolysed ^{14}C-X and phenylacetic acid, by cochromatography on Silica-Gel G thin-layer plates

Enzyme used for the preparation of ^{14}C-X	Solvent	R_f values of ^{14}C-X	Added phenylacetylglycine	HCl-hydrolysed ^{14}C-X	Added phenylacetic acid
R61	*a*	0.77	0.76	0.80	0.80
	b	0.71	0.70		
	c	0.40	0.40	0.56	0.55
R39	*a*	0.78	0.77		
	b	0.71	0.69		
	c	0.36	0.36		

Solvents: *a*, 1-butanol–H_2O–acetic acid–ethanol: 10:4:3:3 (v:v:v:v); *b*, water–1-butanol–acetic acid: 50:10:10 (v:v:v) upper phase; *c*, chloroform–methanol–acetic acid: 88:10:2 (v:v.v).

Note that the R_f values of benzylpenicilloic acid are 0.65 in solvent *a* and 0.55 in solvent *b*. Benzylpenicilloic acid is immobile in solvent *c*.

compound can be reisolated. This technique was applied to ^{14}C-benzylpenicillin (benzyl labelled) and the ^{14}C-X compound produced was isolated.

A solution of R61 enzyme (0.9 µmol; molecular weight 38,000) in 20 ml of phosphate buffer was supplemented at 37 °C with 0.72 µmol of ^{14}C-benzylpenicillin (0.7 mCi mmol^{-1}). Every 30 min, an additional 0.144 µmol of ^{14}C-benzylpenicillin was added until a total amount of 29 µmol of antibiotic was used. Filtration on Sephadex G-25 and elimination of phosphate by addition of acetone at 0 °C yielded 19 µeq of purified ^{14}C-X. Similarly, a solution of R39 enzyme (11.7 nmol; molecular weight 53,000) in 100 µl of Tris-NaCl-$MgCl_2$ buffer was supplemented with 14.5 nmol of ^{14}C-benzylpenicillin (25 mCi mmol^{-1}) and the mixture was incubated for 51 h at 37 °C. Filtration on Sephadex G-25 yielded 4 neq of ^{14}C-X.

The ^{14}C-X obtained with the R61 enzyme was identified as ^{14}C-phenylacetylglycine on the following grounds. (1) Acid hydrolysis with 6 N HCl at 120 °C yielded glycine (yield 100% with the amino acid analyser and 76% after transformation into dinitrophenylglycine) and ^{14}C-phenylacetic acid (as revealed by thin-layer chromatography on Silica-Gel plates using two solvents; Table 1). (2) ^{14}C-X and authentic phenylacetylglycine exhibited the same R_f values by thin-layer chromatography on Silica-Gel plates using three solvents (Table 1). (3) A mixture containing a few neq of ^{14}C-X and a 1,000-fold excess, on a molar basis, of non-radioactive phenylacetylglycine was submitted to three successive crystallisations from ethylacetate. Crystals thus obtained exhibited constant specific radioactivities. (4) The mass spectrum of ^{14}C-X was identical to that given by phenylacetylglycine (Fig. 1). (5) Both ^{14}C-X and phenylacetylglycine, esterified with CH_2N_2, had the same retention time (6 min) by gas–liquid chromatography (at 200 °C, with H_2 and N_2 flow rates of 2 and 30 ml min^{-1}, respectively, and by using a capillary SP1000 column of length 20 m). Similarly, the ^{14}C-X compound obtained with the R39 enzyme was also characterised as ^{14}C-phenylacetylglycine by cocrystallisation and cochromatography with authentic phenylacetylglycine.

We conclude, therefore, that by interacting with benzylpenicillin, both R61 and R39 exocellular enzymes split the antibiotic molecule and that one of the fragments is phenylacetylglycine. Evidently the methylene carbon atom of the glycine residue must arise from C_6 of the penicillin nucleus and, presumably, the C_7 is retained as the glycine carboxyl group (Fig. 2). The fate of the thiazolidine nucleus of the penicillin molecule has not yet been determined. Chemically, benzylpenicillin methyl ester can be degraded to methyl D-5,5-dimethyl-Δ^2-thiazoline-4-carboxylate in trifluoroacetic acid. The N-phenylacetylglycyl fragment was isolated by conversion to its N-benzylamide[8]. A possible mechanism for the action of the *Streptomyces* enzymes would be that the initial event is a rupture of the β-lactam amide bond (Fig. 2; arrow *a*) with attachment of C_7 to some active group in the enzyme By a process of β elimination, in which functional groups of the enzyme could participate, the link between C_5 and C_6 would become a double bond and further degradation would result in removal of the thiazolidine moiety (Fig. 2; arrow *c*). Release of the phenylacetylglycine would then occur. There may be other possible mechanisms and the problem is being studied at present.

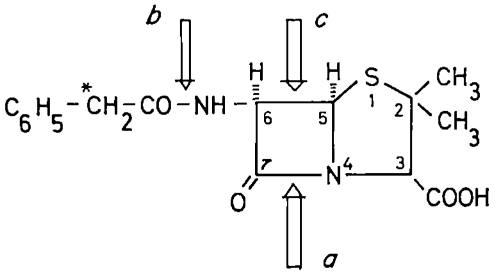

Fig. 2 ^{14}C-benzylpenicillin. *a*, Site of action of penicillinase (reaction product benzylpenicilloic acid); *b*, site of action of amidase (reaction product 6-aminopenicillanic acid); *c* and *a*, possible sites of action of the DD-carboxypeptidase-transpeptidases of *Streptomyces* R61 and R39 (reaction product phenylacetylglycine + unknown). *, [^{14}C].

Whatever the mechanism, however, our studies point to the great importance of the nature of the substituents on C_6 of the penicillin molecule. Substitution at C_6 drastically reduces the activity of the β-lactam antibiotics in all cases tested; 6-methoxypenicillin derivatives, however, remain better inhibitors than the corresponding 6-methyl derivatives[9]. These studies may also be related with the observations of Schmid and Plapp[10] that binding of penicillin to *Proteus mirabilis* was inhibited by phenylacetylglycine and that in the presence of this compound, formation of sphaeroplasts was prevented. Experiments have shown that the extracted and partially purified membrane-bound transpeptidases from *Streptomyces* R61 and *S. rimosus*[5] also perform fragmentation of benzylpenicillin with formation of phenylacetylglycine (M. Leyh-Bouille, J. Dusart and J. M. Ghuysen, unpublished). Moreover, penicillin is known to be degraded into a biologically inactive compound by interacting with the membrane-bound DD-carboxypeptidases of various *Bacillus* spp.[11]. The fact that the membrane-bound targets of penicillin act as antibiotic-degrading compounds is important even if the overall process is slow. It leads to a better understanding of the phenomena of resistance which cannot be explained on the basis of production of either penicillinase or amidase (Fig. 2; arrows *a* and *b*, respectively). It may also be relevant to the necessity for the continuous supply of antibiotic during penicillin therapy.

Scotopic and photopic dark adaptation of the b wave in isolated rat retina

A SLOW form of rod dark adaptation lasting tens of minutes has been observed in isolated retinae[1–5], including those of the rat[6,7], following exposures to intense lights which bleach significant proportions of the rod pigment. Yet in the isolated rat retina in similar circumstances it has been reported[8,9] that the cells which produce the b wave of the electroretinogram adapt within minutes. Since this adaptation is finished before any of the slow thermal reactions of rhodopsin bleaching reach completion, a 'neural' basis for the phenomenon has been suggested. Experiments[10] have, however, confirmed earlier work[11] showing that there is more than one pigment in the rat. This provides an alternative explanation for the fast adaptation of the rat b wave. We have been able to demonstrate that during the fast adaptation the dominant input to the cells producing the b wave comes from the non-rhodopsin pigment system. We have also found conditions in which the b wave shows the slower form of adaptation. Then, the dominant input to the b-wave cells is from a rhodopsin-based mechanism.

Figure 1*a* shows that following the extinction of an intense light which bleaches 70% of, the rhodopsin in the retina, a very rapid adaptation can be seen in the b-wave threshold measurements, a similar phenomenon to that described previously[6,8,9]. From about 6 min the threshold remains stable, except for a very slight decline in the preparation towards the end of 30 min. Frank and Dowling[8] measured thresholds for periods of up to 1 h after a 50% bleach and also reported a stabilisation of the threshold What is new in the present study is that we have demonstrated a permanent spectral shift towards the red in b-wave sensitivity following the light exposure The intensities of the red and blue lights have been equated for their effect on the b wave before the exposure, when, presumably, rhodopsin rods provided the dominant input to the b-wave cells. After the light exposure, the threshold intensities are no longer equal This means that either bleach-increments thresholds for the rat b wave with lights of different wavelengths reaches the rhodopsin molecules, or the b-wave cells are controlled by a non-rhodopsin system Our results are analogous to those of Green[10] who studied increment thresholds for the rat b wave with lights of different wavelengths He too observed a shift in spectral sensitivity towards the red for intense backgrounds, and since this occurred with flashed backgrounds which bleached insignificant amounts of pigment, he interpreted the shift in terms of a transition from scotopic to photopic control of the b wave. It is plausible to interpret our results in the same way. Our conclusion, then, is that the very fast adaptation which we and others have described, reflects processes in a photopic mechanism with a pigment more sensitive to red light than rhodopsin.

Although the b wave shows fast adaptation, the PIII response (the slow component following the b wave and having the opposite polarity) shows the slow adaptation which we have previously reported and which we believe may be linked with the formation of retinol and free opsin at the end of the rhodopsin bleaching sequence[6,7]. PIII, as

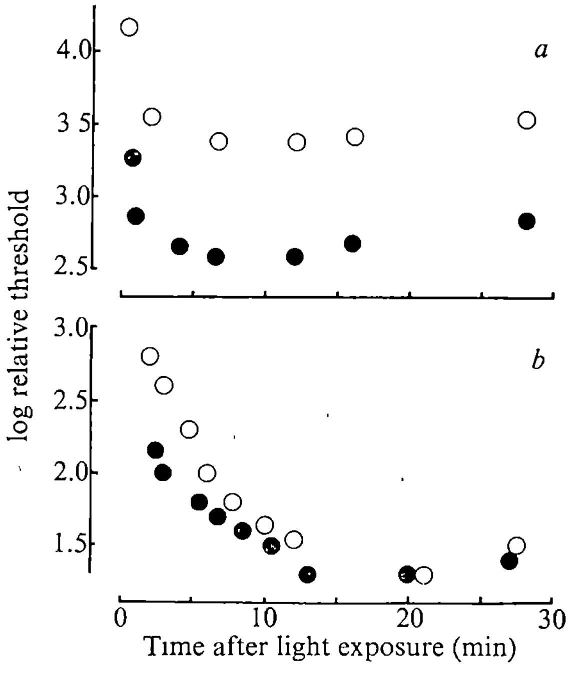

Fig. 1 Adaptation of the b-wave threshold for blue (○) and red (●) stimuli following light exposures which removed 70% (*a*) and 18% (*b*) of the rhodopsin from the dark-adapted retinae. Shimadzu interference filter, $\lambda_m = 482$ nm, used for blue light; Kodak, Wratten 25 filter for red light. b Waves in the range 5–30 μV were elicited from the dark adapted retinae with 50-ms blue and red flashes (frequency response of recording system 0.1–65 Hz). Estimates could thus be made of the calibrated neutral filters required with each type of flash to produce a criterion b wave. The retinae were then exposed to 1 min (*a*) or 25 s (*b*) of unattenuated blue light. At various times following the extinction of the bleaching light, measurements were made of the neutral density values required to elicit criterion b waves. Each of these values was subtracted from the pre-bleach value to provide the data plotted above. Apparatus and preparation details have been given previously[6]. The solution used for perfusion had the following composition (mmol dm^{-3}): NaCl, 119; KCl, 3.4; $NaHCO_3$, 21; NaH_2PO_4, 0.1; Na_2HPO_4, 0 8; $MgSO_4$, 2.4; $CaCl_2$, 2.0; and glucose, 28. It also contained 4% rabbit serum It was bubbled with O_2–CO_2 (95:5) to give a *p*H between 7.6 and 7.9, and its temperature at the retina was 30.5±0.5 °C.

measured here, is largely glial[12] and may have little to do with the signals sent by receptors to other neurones. The rat b wave on the other hand, though it too may have a glial origin[13], is a good index of ganglion cell activity[14]. In our earlier study[6], we therefore questioned how relevant the slow form of PIII adaptation was to understanding the adaptation processes of the rat visual system. Figure 1*b* shows, however, that the slow form of dark adaptation can also be seen in the rat b wave, provided the amount of rhodopsin bleached is relatively small. Although there is some shift in spectral sensitivity towards the red during the initial phase of adaptation, the final post-bleach spectral sensitivity is the same as that before the bleach. We conclude, therefore, that the slow form of adaptation is a property of rods containing rhodopsin. It seems to be very like the slow adaptation seen in the rods of other isolated retinae[1–5]. As Green[10] found in his study on the rat, PIII is always dominated by the rhodopsin-based mechanism. The b wave (and presumably the higher order neurones) will also reflect rod phenomena including slow dark adaptation, provided small amounts of rhodopsin are bleached and the elevation of the threshold is relatively small. On the other hand, for larger bleaches, a photopic mechanism comes to control the b wave. For the living eye and for small pigment bleaches of the isolated retina, this may be transient, but for large bleaches of the isolated retina, the photopic input to the b-wave cells becomes a permanent feature.

These conclusions have implications in the way previous investigations of the rat b wave are interpreted. For example, it has been claimed that a general relationship of the form:

$$\text{log threshold} \propto \text{fraction of pigment bleached}$$

underlies vertebrate dark adaptation. Work on the rat b wave represents one of the key pieces of evidence supporting this relationship (for a review, see ref. 15). The present study, however, makes it clear that many of the threshold measurements on the b wave in adaptation experiments reflect photopic activity and should not be correlated with the state of rhodopsin. Thus, the nature of the relationship between rhodopsin-based responses and the state of the pigment needs to be reconsidered.

We thank Miss A. Miller and J Chalker for technical assistance and the MRC for support.

Inability of the cat to desaturate essential fatty acids

MOST vertebrate species require some dietary source of essential fatty acids (EFAs)[1,2]. A wide range of naturally occurring polyunsaturated fatty acids have been shown to exhibit EFA activity, but they can be classified into two homologous series characterised by the position of the terminal double bonds relative to the methyl (omega) carbon atom. The ω6 series of EFAs all have double bonds in the ω6 and ω9 positions, the ω3 series in the ω3, ω6 and ω9 positions. The metabolic interrelationships of the members of each series are shown in Fig. 1. The naturally occurring 18-carbon parent compounds for each series are linoleic acid (18:2ω6) and linolenic acid (18:3ω3) and EFA requirements are usually stated in terms of either or both of these parent EFAs (p-EFAs)[1,3].

Animal experiments, however, indicate that the higher homologues of the p-EFAs are the physiologically essential compounds[1]. The dietary importance of the p-EFAs probably results solely from their role as precursors of these higher homologues, the derived EFAs (d-EFAs). Studies in the rat have shown that the desaturation steps involved in the production of d-EFAs do not always proceed at an optimal rate, being relatively easily inhibited by dietary or metabolic factors[4,5]. We report here the results of dietary studies on the domestic cat which indicate that this species may lack the ability to further desaturate polyunsaturated fatty acids, and therefore exhibit a specific requirement for lipid of animal origin.

Cats (*Felis catus* L., domestic cross) were bred in this laboratory and when they weighed 0.8–1.7 kg were placed on purified experimental diets which avoided the use of animal lipids likely to be rich in d-EFAs. The two experimental diets used were based on casein (550 g kg^{-1}) and added oil (150 g kg^{-1}). This oil was safflower seed oil in the SSO diet; and a 5:1 (w/w) mixture of soybean oil and linseed oil in the SBOL diet. Both diets contained high levels of cholecalciferol (2.5 mg kg^{-1} diet) but otherwise were designed to satisfy the known nutrient requirements of the cat[6,7]. The control diet was a mixture of proprietary meat- and fish-based cat foods. It contained, on a dry weight basis, 450 g kg^{-1} crude protein and 180 g kg^{-1} lipid, and has proved satisfactory for maintaining our cat colony. The fatty acid composition of the diets is shown in Table 1. One male and one female were fed the SSO diet, two males and three females the SBOL diet and two males and two females the control diet for an average period of fifteen months (range 12 to 18 months).

The fatty acid composition of phosphoglycerides of plasma and red blood cells was examined by standard techniques[8]. The results obtained for plasma choline phosphoglycerides (CPGs) are shown in Table 2; ethanolamine phosphoglyceride and CPGs of red blood cells showed parallel changes. The tissue levels of d-EFAs were much reduced in experimental animals, only arachidonic acid (20:4ω6) and 11,14-eicosadienoic acid (20:2ω6) being present in detectable amounts. That these low levels occur in spite of the presence of very high amounts of

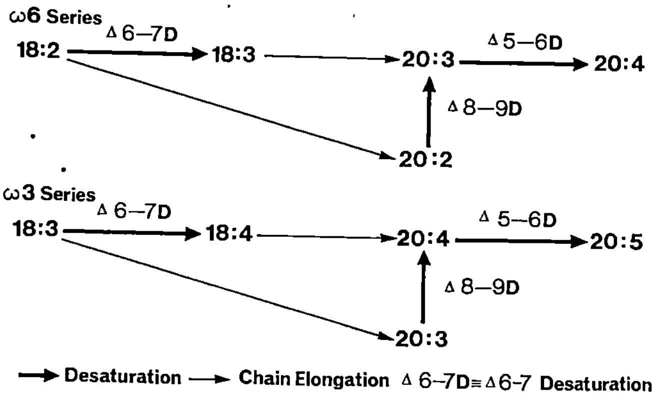

Fig. 1 Metabolism of the essential fatty acids (omitting the 22-carbon fatty acids).

18:2ω6 in diet and tissue lipids, suggests that the experimental animals are unable to chain elongate or desaturate 18:2ω6. Since 20:2ω6 is not present in the diet, nor in the plasma CPG of normal cats, its presence in experimental animals demonstrates that chain elongation did occur. Studies in the rat have shown that the preferred pathway for the metabolism of 18:2ω6 involves a Δ6–7 desaturation to 18:3ω6 (Fig. 1). The chain elongation of 18:2ω6 to 20:2ω6 is relatively unimportant unless desaturation is impaired, therefore the detection of significant quantities of 20:2ω6 and the virtual absence of desaturation products of 18:2ω6 both imply that the Δ6–7 desaturase activity is lacking. Moreover, the absence of 8,11,14-eicosatrienoic acid (20:3ω6) in spite of the high levels of 20:2ω6 is indicative of the absence of Δ8–9 desaturase activity in the cat. Sprecher[9] has recently reported that Δ8–9 desaturase activity is also absent in the rat.

Animals fed the SBOL diet seemed to have higher levels of 20:4ω6 than the two animals receiving SSO diet, but in our routine gas liquid chromatography system 20:4ω6 cochromatographs with 11,14,17-eicosatrienoic acid (20:3ω3). By the use of a 50-m capillary column we were able to separate these components and show that the 20:4ω6 peak contained about 40% 20:3 ω3. We failed to detect 20:3ω3 in the 20:4ω6 peak of animals fed SSO. We conclude that the plasma CPG levels of 20:4 ω6 were about the same in the two experimental groups and that the presence of 20:3ω3 confirms the absence of Δ6–7 and Δ8–9 desaturase activity with ω3 fatty acids as a substrate.

The unknown fatty acid detected in plasma CPG of animals fed all experimental diets has not yet been identified fully. We have established that it is a 20-carbon straight chain fatty acid and that it does not belong to the ω3, ω6 or ω9 series. Investigations into its structure are continuing.

Fatty acids as g per 100 g total fatty acids as mean (± s.e.m. where appropriate).

—, Indicates compound not detected (limit of detection about 0.04 g per 100 g fatty acids).

Animals fed the experimental diets showed a varied clinical picture. All were listless, however, and had dry staring coats and severe dandruff. They grew poorly and seemed to be severely affected by infections and stress. Histological examination of their livers showed much fatty infiltration and parenchymal disorganisation. Both male and female animals became behaviourally infertile on the experimental diets, testes were underdeveloped and vaginal smearing failed to demonstrate the occurrence of oestrous cycles. We cannot explain these effects as a result of the level of dietary vitamin D, and, although limited by the lack of a suitable control group, there seems to be a similarity in this clinical picture with that caused in other species by feeding diets lacking in EFA activity[1,10]. Few attempts have been made to feed cats defined diets for prolonged periods, but these have resulted in reduced growth and failure to breed[11]. It may well be that deficiency of d-EFAs in purified diets caused these defects.

So far, one female SBOL animal has been returned to the control diet. This caused a rapid and sustained change in the fatty acid pattern of plasma CPGs (Table 3) and a marked improvement in clinical state. The animal rapidly gained weight (0.5 kg in 32 d), its coat became thicker and glossier and the dandruff disappeared. Its behaviour altered—the animal becoming more friendly and less restless. On day 32 of refeeding the animal came into oestrus and was successfully mated: after an uncomplicated pregnancy she gave birth to, and suckled, four normal young.

Table 3 Changes in essential fatty acids of plasma CPG in a SBOL cat refed control diet

—, Indicates compound not detected (limit of detection about 0.04 g per 100 g total fatty acid).

Our observations clearly indicate a lack of Δ6–7 and Δ8–9 desaturase activity in the cat. Preliminary results (J.R. and A.J.S., unpublished) indicate that the Δ5–6 desaturase activity is lacking so that conversion of 20:3ω6 to 20:4ω6 cannot occur.

We conclude that the EFA requirement of the cat can only be satisfied by a diet containing d-EFAs, regardless of the dietary levels of p-EFAs. This phenomenon has not previously been described in any animal species; however, a d-EFA requirement would explain an observation that animal lipid was a necessary dietary component for optimal health in mink[12]. Classically, EFA deficiency is identified by an increase in tissue levels of 5,8,11-eicosatrienoic acid (20:3ω9), a non-essential derivative of oleic acid synthesised by animals fed diets deficient in EFA. We did not observe 20:3ω9 in our animals, a further indication of the absence of Δ6–7 and Δ5–6 desaturases. We postulate that a total EFA deficiency could be induced in the cat without significant levels of 20:3ω9 being produced.

The absence of desaturase activity in the cat makes it a particularly good experimental model for research on prostaglandins and essential fatty acid metabolism. The possibility that other species adapted to an omnivorous or carnivorous diet might show a d-EFA requirement also deserves investigation.

Folate-dependent 1-carbon transfer to biogenic amines mediated by methylenetetrahydrofolate reductase

IT has been suggested that N-methylation of biogenic amines is involved in the development of certain schizophrenic disorders[1,2]. Interest in this transmethylation hypothesis has been boosted by the reported identification of a mammalian N-methyltransferase ("dopamine methyltransferase"[3]) which uses as methyl donor N^5-methyltetrahydrofolate (MTHF) rather than S-adenosyl methionine[3–5]. Further studies have demonstrated that the products of the incubation of catecholamines or indoleamines with MTHF and the transferase were not N-methylated amines but tetrahydroisoquinoline or tetrahydro-β-carboline alkaloids, respectively[6–10]. These compounds can be formed readily by the condensation of formaldehyde with the amines and it has therefore been postulated that the enzyme originally identified as a methyltransferase may in fact act to release formaldehyde from MTHF[6–10]. We provide evidence that the enzyme methylenetetrahydrofolate reductase (EC 1.1.1.68) is responsible for the reported production of formaldehyde from MTHF.

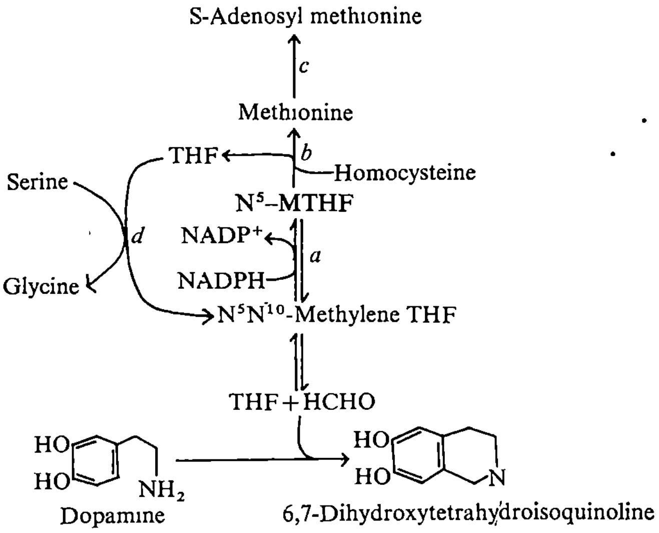

Fig. 1 Folate metabolism and tetrahydroisoquinoline synthesis. The enzymes involved are: *a*, methylenetetrahydrofolate reductase (EC 1.1.1.68); *b*, N^5-MTHF homocysteine methyltransferase (EC 2.1.1.13); *c*, methionine adenosyltransferase (EC 2.5.1.6); *d*, serine hydroxymethyltransferase (EC 2.1.2.1) The dissociation of methylenetetrahydrofolate to tetrahydrofolate and formaldehyde and the reaction of formaldehyde with dopamine are presumed to be non-enzymic.

Methylenetetrahydrofolate reductase catalyses the NADPH-dependent reduction of N^5,N^{10}-methylenetetrahydrofolate to MTHF (see Fig. 1). In the reverse direction, in the presence of a suitable oxidant, MTHF is converted to methylenetetrahydrofolate which may dissociate to tetrahydrofolate and formaldehyde[11]. The release of formaldehyde from MTHF may be used as an assay procedure, but the reductase may also be assayed spectrophotometrically in the direction of MTHF formation[11]. In this work both assays have been used and dopamine methyltransferase was measured radiometrically as described by Laduron[3].

High activities of both methylenetetrahydrofolate reductase[11] and dopamine methyltransferase[5] are reported to occur in liver, and this tissue was used for most of the studies reported here. The reductase was purified to a specific activity of 0.1 U mg^{-1} as described by Kutzbach and Stokstad[11] and the activities of the reductase and of dopamine methyltransferase copurified during this procedure. The product was further fractionated by gel filtration or isoelectric focusing.

Gel filtration was performed on a calibrated Sephadex G-200 column and the eluate was assayed for methylenetetrahydrofolate reductase and dopamine methyltransferase. Both activities coincided in a single symmetrical peak with an elution volume corresponding to an apparent molecular weight of 170,000–190,000 (Fig. 2*a*). Both methylenetetrahydrofolate reductase and dopamine methyltransferase were recovered in a single peak corresponding to an

Table 1 Effect of various additives on the activities of methylenetetrahydrofolate reductase and dopamine methyltransferase

Additive	Methylenetetrahydrofolate reductase activity (%)	Dopamine methyltransferase activity (%)
None	100	100
FAD (2×10^{-6} M)	410	320
DOPAC (1×10^{-2} M)	47	58
S-Adenosyl methionine ($1 6\times10^{-4}$ M)	< 10	< 10
S-Adenosyl methionine (1.6×10^{-4} M) +S-adenosyl homocysteine (1.6×10^{-4} M)	54	100

Methylenetetrahydrofolate reductase was purified from pig liver as described in the text and its activity was measured spectrophotometrically at 340 nm as described by Kutzbach and Stokstad[11]. Dopamine methyltransferase was assayed radiometrically as described by Laduron[3].

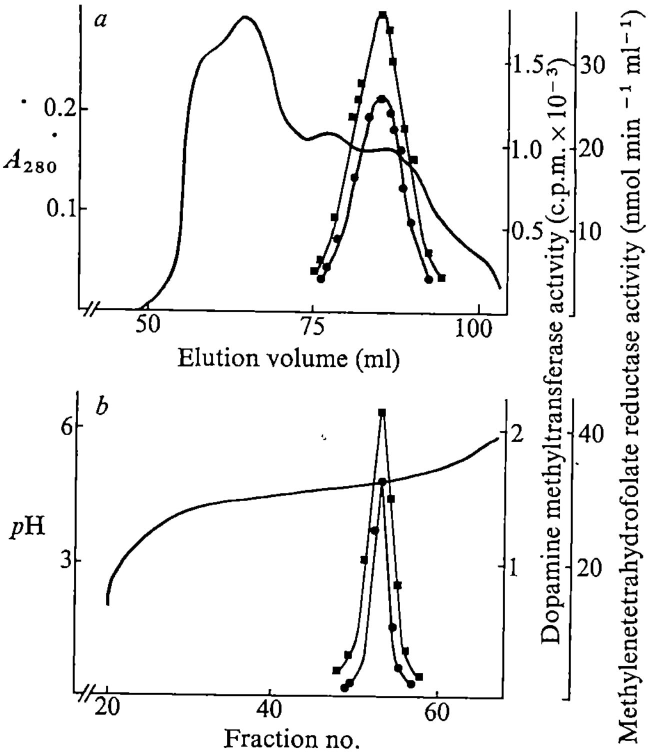

Fig. 2 *a*, Isolation of methylenetetrahydrofolate reductase by gel filtration on Sephadex G-200. 10 mg methylenetetrahydrofolate reductase (specific activity, 0.1 U mg^{-1}) purified from pig liver by the method of Kutzbach and Stokstad[11] was applied to a Sephadex G-200 column (1.5×95 cm) equilibrated in 10 mM potassium phosphate buffer, *p*H 7.5 containing 1 mM EDTA and 1 mM mercaptoethanol. Fractions were assayed for protein (A_{280}) and for methylenetetrahydrofolate reductase (●) and dopamine methyltransferase (■) activities as described in the text. *b*, Isoelectric focusing of methylenetetrahydrofolate reductase. 10 mg methylenetetrahydrofolate reductase was electrofocused at 4 °C in a 110 ml LKB column using ampholine, *p*H 3.5–5.0, in a 20–60% glycerol gradient. When electrofocusing was complete the column was drained and 2 ml fractions were collected. The *p*H value and the activities of methylenetetrahydrofolate reductase (●) and dopamine methyltransferase (■) of the fractions were measured. The recovery of enzyme activity was 50–60%.

isoelectric point of 4.8 (Fig. 2*b*). A similar result was obtained when dopamine methyltransferase, partially purified from bovine brain by the method of Laduron[4], was assayed by isoelectric focusing.

Active fractions from the gel filtration column were pooled and concentrated and used to investigate the effects of several additives on enzyme activity. The assay procedure for methylenetetrahydrofolate reductase routinely includes the addition of 2 μM FAD which produces a fourfold stimulation of the rate observed in the absence of the flavin coenzyme[11] and, correspondingly, the activity of dopamine methyltransferase was shown to be significantly increased in the presence of FAD (Table 1) 3,4-Dihydroxyphenylacetic acid (DOPAC) has been reported to inhibit the transferase[12]. We observed that 10^{-2} M DOPAC inhibited both the transferase and methylenetetrahydrofolate reductase activities to similar extents (Table 1).

Methylenetetrahydrofolate reductase is the initial enzyme in the pathway leading to the synthesis of S-adenosyl methionine (see Fig. 1). The reductase is allosterically inhibited by S-adenosyl methionine and this inhibition is relieved by S-adenosyl homocysteine[11]. As shown in Table 1, 1.6×10^{-4} M S-adenosyl methionine inhibited both the reductase and the transferase to similar extents and this inhibition was indeed reversed by S-adenosyl homocysteine.

The evidence presented here therefore supports the hypothesis that methylenetetrahydrofolate reductase and dopamine methyltransferase represent two activities exhibited by a single enzyme species. It is noteworthy that the regional distribution of these two activities in brain have previously been shown to be similar[13,14]. The mechanism of 1-carbon transfer to biogenic amines by the reductase *in vitro* would seem to involve oxidation of MTHF to methylenetetrahydrofolate and subsequent non-enzymic dissociation of formaldehyde from the folate derivative (Fig. 1). It is, at present, uncertain whether mediation in the synthesis of tetrahydroisoquinoline and tetrahydro-β-carboline alkaloids represents a physiological activity of this enzyme. Both the equilibrium of the reaction[11] and the NADPH–NADP$^+$ ratio in the cytosol[15] would favour MTHF synthesis rather than the reverse reaction involving formaldehyde release. Furthermore, free formaldehyde may also bind to tissue protein[16] or be oxidised by formaldehyde dehydrogenase[17]. The feedback inhibition of methylenetetrahydrofolate reductase by S-adenosyl methionine also supports the concept that the physiological function of this enzyme is in the ultimate synthesis of S-adenosyl methionine rather than the metabolism of biogenic amines. Since the formation of pharmacologically active alkaloids[18] from MTHF and amines may be detected *in vitro*, however, it would seem to be important to investigate their possible formation *in vivo*.

Lunar magnetism

In a recent series of papers, Runcorn[1,2] has maintained that the observation of a very small lunar surface dipole field ($\lesssim 0.05\gamma$) implies that there used to be a fairly strong interior lunar dipole moment ($\gtrsim 3.2\times10^9$ yr ago). He contends that if such a field had disappeared in the past 3.2×10^9 yr, the exterior field of the Moon would now be zero. This, he argues, is a direct result from potential theory.

I show, for a very simple model of the Moon, that if a primordial core magnetic field existed, it would give rise to a present day non-zero dipole external field.

Consider a uniformly magnetised core of radius a, embedded in a permeable mantle with outer radius b. The core magnetisation is $M_0 = M_0\hat{e}_3$ and the scalar potential of the magnetic field, H, satisfies $H = -\nabla\varphi(x)$, with $B \sim \mu H$ in the mantle. The boundary value problem is easily solved with the result.

$$\Phi_C(x) = \alpha r \cos\theta \tag{1}$$

$$\Phi_M(x) = (\beta r + \gamma/r^2)\cos\theta \tag{2}$$

$$\Phi_V(x) = \delta/r^2 \tag{3}$$

where C, M, and V refer to core, mantle, and vacuum, respectively; and

$$\begin{aligned} \alpha &= \beta + \gamma/a^3 \\ \beta &= -2(1-\mu)A \\ \gamma &= b^3(\mu+2)A \\ \delta &= 3\mu b^3 A \\ A &= 4\pi M_0 a^3/D \\ D &= (2\mu+1)(\mu+2)b^3 - 2a^3(1-\mu)^2 \end{aligned} \tag{4}$$

Now imagine that the magnetising currents in the core die out.

The magnetisation of the mantle in the absence of a core field is then

$$M(x) = \frac{(\mu-1)}{4\pi}\left[-\beta + \frac{2\gamma}{r^3}\right]\cos\theta\hat{e}_r + \left[\beta + \frac{\gamma}{r^3}\right]\sin\theta\hat{e}_\theta \tag{5}$$

The scalar potential, $\Psi(x)$, of the resulting field is

$$\Psi_C(x) = -\frac{2}{3}\frac{(\mu-1)}{a^3}(1 - a^3/b^3) \times \times \gamma r\cos\theta \tag{6}$$

$$\Psi_M(x) = \frac{(\mu-1)}{3}[\beta(a^3 - r^3) - -2\gamma(1 - r^3/b^3)]\frac{\cos\theta}{r^2} \tag{7}$$

$$\Psi_V(x) = \frac{(\mu-1)}{3}(b^3 - a^3)\beta\frac{\cos\theta}{r^2} \tag{8}$$

Equation (8) leads to a non-zero external dipole field. Runcorn's conclusion[1,2], that the external field is zero, is based on his assertion that the potential of the magnetising field has the form of equation (2), but with $\beta = 0$. Clearly, if $\beta = 0$ in equation (2), then $\Psi_V(x) = 0$. It must be emphasised that, using an internal magnetising field, the external field is in general non-zero after the core field has decayed to zero. The solution given by equations (6)–(8) is, in fact, a linear combination of the 'interior' and 'exterior' solutions discussed by Runcorn[2].

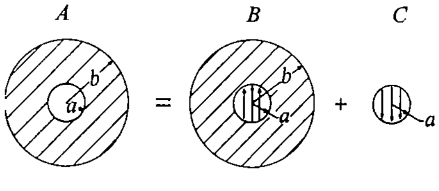

Fig. 1 The superposition of the magnetic fields. The field in A where there is no core magnetisation can be derived by subtracting the field of a uniformly magnetised sphere, radius a, (C) from that of the large uniformly magnetised sphere (B). See the equations for details.

The conclusion that the external field is not zero also follows from the linearity of the magnetostatic field equations. The solution of the problem with zero core field can be obtained from the solution with non-zero field, equations (1)–(4), by adding to the fields derived from equations (1)–(4), the field of a uniformly magnetised sphere of radius a, with magnetisation $M' = -M_0\hat{e}_3$. This is indicated schematically in Fig. 1. The resulting external field will clearly be a dipole of reduced strength. The fields resulting from such a superposition are in fact identical to those resulting from equations (7) and (8).

Stephenson *et al.*[3] note that Runcorn's result is strictly true only if the magnetic susceptibility of the mantle is very small, $\sim 10^{-4}$. Although it is clear that the exterior field is of higher order in $(1-\mu)$ than the fields in the other two regions, one must be cautious about arguing that it is therefore negligible. The permeability has been treated as though it were paramagnetic in this simple derivation, but it must, of necessity, be ferromagnetic. To my knowledge the ferromagnetic permeability of the Moon is not known. Dyal *et al.*[4] have, however, found a paramagnetic permeability $\mu \sim 1.01$, that already is larger than the value of $1 + 10^{-4}$ used by Stephenson *et al.*[3]. This larger value for μ implies the existence of ferromagnetic material[4], the properties of which are undetermined.

I acknowledge discussions with Dr N. F. Ness and J. D. Scudder.

RUNCORN REPLIES—The theorem[1,2] which I proved is exactly correct as I stated it: that is, if a spherical shell of any thickness acquires permanent magnetisation, the intensity of which is proportional and parallel to a magnetising field of internal origin, which later disappears, its external field is zero. In the simpler proof[1], the magnetising field was assumed to be that of a centred dipole and I used the theorem to show that the new determination[3] of the present lunar dipole magnetic field as $< 1.3 \times 10^{18}$ gauss cm^3, or $< 0.05\ \gamma$ at the equator (essentially negligible), is very powerful evidence for the existence of an ancient lunar magnetic field of internal origin, which had been postulated to explain the natural remanent magnetisation discovered in the lavas returned by the Apollo missions[4], and effectively excludes an external agency unless it resulted in random magnetisation.

It was shown[2] that if the maximum magnetisation of the shell at its exterior is I, then, for the dipole case, there is within its inner boundary, a uniform field of intensity $4\pi\ I/3$ times the ratio of the volume of the shell to that of the unmagnetised inner sphere. If the depth of the Curie point isotherm is taken as 50 km, this ratio is 0.1, and if $I = 10^{-4}$ e.m.u. g^{-1} the uniform field is 10 γ.

I was aware that such a field, derived from the outer part of the magnetised shell, not only induces magnetisation in its interior, the point of Goldstein's communication, but would also have modified the magnetising field in which the rocks, cooling through the Curie point, acquired thermoremanent magnetisation. The resultant component of uniform magnetisation of the shell, increasing inwards, will give rise to an external dipole field, as will the departure of the Moon from sphericity, but I considered these effects and found them negligible[2]. Goldstein incorrectly quotes us in the last paragraph: we[6] stated that, for the theorem to be applicable, c, the magnetisation acquired in unit field, must be very small, of the order of 10^{-4}, not the magnetic susceptibility ($\mu - 1$) which even if it is 10^{-2}, as one analysis gives[7], produces a dipole field of much less than the observable limit. As the equatorial surface field of a shell, of uniform magnetisation I', is $4\ \pi\ I'/3$ multiplied by the ratio of the volumes of the shell to the sphere, this external field is about 0.01 γ for the Moon.

In devising a mathematical model to describe and understand the significance of experimental data, the scientist simplifies the physical situation by leaving out of consideration factors which are unimportant. Lyttleton[8] has lately reminded geophysicists of Eddington's description of the process. It is entirely legitimate for the mathematician to point out that the most general expression has not been used, but he must show quantitatively that with this added complexity, observations can be better fitted or the inferences to be drawn are thereby qualitatively changed; Goldstein does neither. But perhaps when the accuracy and reliability of magnetometers carried in spacecraft is improved by orders of magnitude, the further refinement of the theorem will be necessary. Goldstein may be drawing an analogy with the Earth—often misleading for lunar scientists—where the induced magnetisation of geological formations is usually of the same order as the permanent magnetisation.

Effects of gallic acid on nitrosamine formation

OBSERVATIONS[1] on the catalytic effect of the naturally occurring polyphenol, chlorogenic acid, on the nitrosation of piperidine, may be supplemented by similar observations we have made during an investigation into the effect of gallic acid—an essential constituent of the gallotannins—on nitrosation of diethylamine. The possibility that such compounds could exert an influence on the *in vivo* formation of carcinogenic nitrosamines deserves careful attention.

Though early experiments[2] established the existence of an impeding effect by tannins on the formation of nitrosamines, more recent work shows that the amount of nitrosamine formed is dependent both on the *p*H and the concentration of the gallic acid.

We reacted concentrations of nitrite (0.075 M) and diethylamine (0.5 M) in buffered aqueous solutions, in the presence of different concentrations of gallic acid. Reaction was allowed to proceed for 30 min after which the solution was made alkaline to stop further reaction, and extracted with methylene chloride. The concentration of nitrosamine was determined using both ultraviolet spectrophotometry and gas chromatography. The concentrations of both the nitrite and the amine were chosen to give a convenient yield of nitrosodiethylamine for measurement of both systems. The relatively high concentration of amine allowed the use of a lower concentration of nitrite so that the competitive reaction of nitrite with gallic acid was not masked.

The results show (Fig. 1) that although gallic acid does exert a catalytic effect, it is extremely dependent on *p*H and is restricted to a narrow range in the region of *p*H 4. In addition, the balance between the retarding and catalytic effect is strongly dependent on the concentration of gallic acid, as illustrated by the fact that an increase in the formation of nitrosamine related almost linearly with a decrease in the concentration of gallic acid. Similar effects were also found when solutions of tannic acid were used in place of gallic acid.

Though this tends to support the views of Challis and Bartlett[1], the idea that a catalytic effect by natural phenols can lead to the *in vivo* formation of nitrosamines, should be considered with caution. Nitrosamine formation could be dependent on the variable *p*H conditions in the digestive system and on eating and drinking habits which could regulate the simultaneous concentrations of nitrite, tannins and nitrosatable amines that may have been ingested or formed in the system.

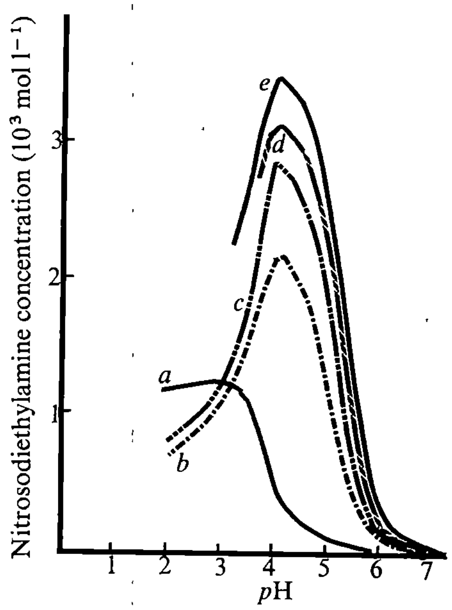

Fig. 1 Diagram demonstrating the increasing catalytic effect of gallic acid on nitrosodiethylamine formation with decreasing concentrations of gallic acid. Gallic acid concentration: *a*, 0; *b*, 0.0625 M; *c*, 0.0375 M; *d*, 0.025 M; *e*, 0.0125 M.

Antibody molecule

R. R. Porter

The Antibody Molecule. (Immunology: An International Series of Monographs and Treatises.) By Alfred Nisonoff, John E. Hopper and Susan B. Spring. Pp. xiv+542. (Academic: New York, San Francisco and London, August 1975.) $34.50; £16.55.

THE capacity of those individuals who survive infectious diseases to become immune to further attack was recognised early in history, and for several hundred years attempts have been made to exploit this phenomenon in medicine. It is nearly one hundred years since Behring showed that the substances which are responsible are present in the blood of the immune animal and named them antibodies, but it is less than twenty years since advances in knowledge of protein chemistry made it possible to isolate and study the structure of these remarkable molecules. Their fascination lies in the ability of almost identical molecules to combine specifically with an apparently endless range of different substances and the recognition that this phenomenon is essential for the survival of all species of vertebrates. The growing realisation that a related phenomenon may be the basis of cellular recognition and therefore be an important feature of differentiation has put the antibody molecule in a key position in biological research. Here for the first time, the variable region of antibody molecules offers a chemical basis for one aspect of the infinite variety of living things. The genetic origin of this very wide range of protein structures found in all individuals remains a mystery, but one likely to be solved soon.

Even so, it is surprising to find in this book just how much information has been acquired in so short a time. The emphasis throughout the book is on the structure of the immunoglobulins, the proteins which carry the antibody activity. The chemical structures which define the division of the immunoglobulins into class and subclass, type and subtype, the different polymorphic forms, and the amino acid sequence changes found in the variable regions are all well described Most of this work is soundly based, and although much remains to be investigated sufficient detailed study has been carried out on the immunoglobulins of several species to provide a body of knowledge which is now the basis for present investigations on the genetics, the control of synthesis and cellular origins of immunoglobulin, and on many other aspects of immunity.

The authors have written an advanced monograph in which a mass of complex data has been presented in a well ordered and comprehensible manner. Sufficient detail is given to make this book an excellent source of reference for those working in the field, but it never obscures the main themes. It should be of equal value for the many biologists with a peripheral interest in the subject. The book has been published quickly: most of the X-ray crystallographic studies of the past year or two are described and a most informative coloured plate has been included of the model of the *Fab* fragment of a human myeloma protein. Enough experimental detail will be found to support the results described and to explain, for example, the discovery of the still somewhat obscure idiotypic specificities of antibodies.

Most of the work described is of immediate interest, but some, such as the early attempts to define the relative contribution of the heavy and light chain of antibodies to the structure of the combining site, have a dated flavour and already seem to have been superseded by subsequent knowledge of the chemistry and crystallographic studies of the variable regions. Succinct accounts are included of the brief histories of most of the topics discussed and are incomplete only in the overmodest absence of references to the senior author. Careful reading of the extensive bibliographies at the end of each chapter is necessary to appreciate how large a contribution to our knowledge of antibody structure has been made by Dr Nisonoff.

This book gives a clear account of our factual knowledge of the structure of antibodies and of its biological significance It is likely to remain of enduring value for some years to come.

Man and wildlife

Man and Wildlife. (Biology and Environment.) By L Harrison Matthews. Pp. 129+16 plates (Croom Helm: London, September 1975.) £4.95.

WE have been here many times before—from early man and increasing plunder of wildlife to population explosion and pollution—but this is a very readable addition to the considerable clutch of similar books.

The detailed effects of man's impact on wildlife (and vice versa) are discussed in convenient form. There are chapters on plants and topography, the sea, marine mammals, birds, insects, and other invertebrates, followed by one on "Conservation Profit and Loss" and a rather curious bibliography for further reading.

The authoritative and lively style is to be welcomed Not so, instances of what seems to be prejudice leading to dubious generalisation and emotive references out of tune with the character of the book As an example, "superficial" wildlife films on television as well as bird watchers with their "little" lists are castigated without acknowledgement that herein may lie the genesis of funds for holding open the conservation options for future generations— to purchase Wash and Lake Nakuru mud, and to pay for 'Operation Tiger' and education all over the world.

The Publishers' note on the wrapper expressing some hope for wildlife's future is clearly not endorsed by the author in his concluding chapter which omits adequate analysis of the conservation effort. Yet if we are to accept that all hope is lost at this stage, much of the *raison d'être* of civilised man is lost also.

Derek Barber

Cognitive aspects of reading

The Psychology of Reading. By Eleanor J. Gibson and Harry Levin. Pp. xii+630. (MIT: Reading, Massachusetts and London, 1975.) $18.95.

THE republication of Huey's *Psychology and Pedagogy of Reading* after sixty years of general reticence on the topic has been accompanied by a rush of modern treatments. This rebirth of interest in reading reflects not only the cunning propensity of psychology for crop rotation but also an increasing interest of cognitive psychologists in skilled and intelligent performance. At the same time social concern about literacy, especially in the US, has enabled the psychologist, like a modern Danaë, to be possessed by Zeus in a shower of research funds. This volume by Gibson and Levin presents the most comprehensive engagement to date of cognitive psychology with the problem of reading.

The book consists of three sections, the first of which reviews the basic psychological and linguistic principles which the authors believe relevant. These include perceptual learning, work on general, cognitive and especially language development, basic linguistics and some specialised material on writing systems, and finally, a discussion of the considerable literature on the visual perception of words

It is this extensive review section which sets the book apart and, in a sense, exhibits its academic credentials. The result is not entirely satisfactory. One problem is that the survey has something of the texture of 'annual review' articles, dense and impressively referenced but somehow lacking in coherence. The mass of data is insufficiently organised to be readily digested by the non-psychologist or to provide new insight for the specialist. Significantly, the introductory chapters on linguistics and writing systems are much more readable than those reviewing areas of experimental psychology. There are some obscurities, such as the curious description of Spoehr and Smith's research on pages 91–92 and the seemingly contradictory claims about the effect of orthographic regularity on letter search. But on the whole the text is dry and lucid.

The treatment of underlying concepts is lengthy yet some judgements have been made about exclusion of material. Notable absences include vision research such as metacontrast, much of the post-Sperling work on letter array processing and the important work of Meyer on lexical decisions. There is also little explicit treatment of general problems of pattern recognition.

The core of the book is the section on the reading process itself This is rather more readable, not least because the view of basic questions is less obscured by an untidy forest of experimental data. This section should also prove fruitful to the non-specialist. It concludes with a review of models of skilled reading, which brings the discussion back to the preoccupations of experimental psychology. Here, in an attempt to invent some substantive issues the authors create a curious opposiion of 'information processing' and 'analysis-by-synthesis' models. This chapter also contains one of the occassional lapses into slightly partial reviewing, where (page 467) the claims of Gibson and her colleagues about an absence of acoustic or semantic effects on visual search are presented without mention of conflicting evidence.

The final section consists of short capsules for such questions as dyslexia and speed reading Of these the freshest and most absorbing is on cross-language differences in reading achievement. Here is set out the baffling lack of well established relationship between reading development and the vastly different forms of orthography. This is almost enough to terminate the cognitive psychologist's flirtation with the real world. One echoes the words of a recent article title: "Do not adjust your mind, there is a fault in reality."

Huey's classic book is a more provocative essay on reading and the recent experimental literature is more penetratingly treated elsewhere, but Gibson and Levin have produced a scholarly and comprehensive textbook. Like boxed sets of symphonies there is a simple virtue in completeness.

Leslie Henderson

Life gaining ground

Surtsey: Evolution of Life on a Volcanic Island. By Sturla Fridriksson. Pp. 198. (Butterworth: London, 1975.) £5.00.

ON November 14, 1963, a submarine volcanic eruption began in the ocean south of the Westman Islands off the coast of Iceland, which eventually resulted in the production of an island with an area of 2.5 square kilometres. The island was aptly named Surtsey, after the mythical Norse fire-giant, Surtur the Black. The geological significance of this rare event was immediately apparent, but the biological opportunities presented by the occurrence are of no lesser importance. These were fortunately recognised by men such as Sturla Fridriksson, who visited the island within six months of its formation and began the formidable task of documenting the establishment of living organisms.

The succession of life on totally bare areas of land surface has not been studied intensively, mainly because of the lack of opportunity, especially in isolated situations where invasion demands very effective dispersal on the part of the organism concerned. Students must surely be weary of the much repeated but rather fragmentary information available from Krakatoa following its eruption in 1883. But in this new book, Fridriksson has summarised the development of living communities of organisms and simple ecosystems in the 10 years since the formation of Surtsey.

The study is extensive. It documents the establishment of microbial life within months of the initial eruption, and the arrival of the first invertebrate terrestrial animals, birds and viable seeds. Complete lists of plant invaders (including bryophytes) are given, with details of when they arrived. Bird life is also covered in detail, the book largely being concerned with visiting species, but also recording with some pride the establishment of breeding pairs of fulmar and black guillemot. Arthropods are dealt with in less detail; 158 species have now been recorded, but many of these could have failed to establish themselves as permanent inhabitants.

The chapter on "Ways of Dispersal" is particularly interesting in that it deals with mechanisms by which dispersal (mainly botanical) has been effected. Some species, such as *Senecio vulgaris* and *Eriophorum scheuchzeri* have been observed during invasion by air-borne seeds. A surprising list is given of seeds found attached to the egg cases of skate and washed up on the island; many grasses arrived in that manner. Some seed eating birds (snow buntings) were found to have viable seeds in their gizzards, which could potentially provide an invasion mechanism.

Finally, the developing biota of Surtsey is compared with neighbouring islands and the mainland of Iceland, and naturally these seem to provide the major source areas for invaders.

The book is well illustrated with some spectacular colour photographs as well as a large number of line drawings and maps. It is written in a lively, informal manner, which effectively conveys Fridriksson's vigour and his enthusiastic concern to observe the ecological development of a truly pristine habitat.

P. D. Moore

Liquid column chromatography

Liquid Column Chromatography: A Survey of Modern Techniques and Applications. (Journal of Chromatography Library, Volume 3.) Edited by Zdenek Deyl, Karel Macek and Jaroslav Janak. Pp. xxi+1,175. (Elsevier Scientific: Amsterdam, London and New York, 1975.) Dfl. 290; $120 95

THIS collaborative 1,120-page volume, almost entirely the work of a group of Czech authors, is undoubtedly the most comprehensive account of the subject currently available It is divided into four main sections: theoretical aspects of liquid chromatography, techniques of liquid chromatography, practice of liquid chromatography, and applications. The first three sections are general and make up about one-third (413 pages) of the book, whereas the application of these methods to specialised classes of compounds make up the remaining two-thirds.

The general theoretical section is in some respects the least successful part of the book, as in my opinion too much attention is paid to mathematical rigour and insufficient space (only some 10 pages) to the factors which influence zone resolution in practical chromatography. The short section on the thermodynamics of partition and adsorption processes by Novak, however, is excellent. It is rather disappointing to find the old but fallacious concept of a direct relation between solute molecular weight and retention volume adopted in all the sections on gel permeation (or molecular-sieve) chromatography.

The second and third sections on the techniques and practice of liquid column chromatography are excellent The editors explain that they have decided, wisely in my view, to give equal prominence to the "classical" methods of liquid chromatography and to the newer techniques of high efficiency, high pressure chromatography, especially as the former still constitute 90% of published methods. The techniques section is essentially confined to instrumentation and materials (mobile and stationary phases) for all the fundamental subgroups of chromatography, adsorption, partition, ion-exchange and the exciting new development of affinity chromatography. The chapters (8 and 11) on instrumentation and operation of high efficiency, high pressure systems compare favourably with some of the specialised works on the subject. Chapter 9 on stationary phases and chapter 10 on mobile phases are particularly valuable, and are admirably complemented by the corresponding chapters 13 and 14 in the practice section. These sections include extensive tables of the properties of the relevant stationary and support phases, as well as those of mobile phase solvents. The criteria for choice of phase, and packing, conditioning and operation of column receive special attention. The sections throughout the book contributed by Dr O Mikes on ion-exchange chromatography and by Mrs J. Turkova on affinity chromatography must be specially commended.

The special section of the book gives detailed recommendations for the chromatographic separation of a variety of chemical compounds ranging through hydrocarbons, alcohols through carbohydrates, lipids, amino acids peptides and proteins, nucleic acids and their constituents to some specialised classes of organic compounds such as vitamins, antibodies and pesticides, to cells and subcellular particles, and finally to inorganic compounds

It is always difficult to assess the value of such large specialised sections in any book, as only a small portion of the material presented will be of any value or even interest to any particular reader, and also such material is more likely to become outdated than general sections. I believe that the best solution is a series of well-documented and indexed tables which will guide the interested reader into the literature of his own subject, without increasing the bulk (and cost) of the book with specialised material of no interest to him.

Among the best of these special chapters are 32 on amino acids by Zmrhal, Heathcote and Washington, 34 on peptides by Khluh, 35 and 36 on proteins by Prusik and Mikes, and 37 and 38 on nucleic acids and their constituents by Zadrazil. These are virtually monographs on their subjects.

In summary, this is by far the best book on liquid column chromatography to appear to date. It is excellently produced, but it is unfortunate that its price will render it inaccessible to many departmental libraries.

C. J. O. R. Morris

Dynamics of galaxies

The Formation and Dynamics of Galaxies—Proceedings of IAU Symposium No 58, Canberra, Australia, 1973. Edited by J. R. Shakeshaft. Pp. xv+441. (Reidel: Dordrecht, Holland; Boston, Massachusetts, 1974.) Cloth Dfl 135, $54.00; paper Dfl. 100, $38.50.

THE publications which arise from IAU symposia are among the most valuable books in any library used by astronomical researchers, and the present round is appearing with commendable speed, given the usual timescale for publication of proceedings volumes. Little has happened since August 1973 to reduce the value of these contributions from the leading lights in cosmology and cosmogeny who were then assembled in Canberra; on the other hand, by the very nature of the book many of the contributions have a familiar ring about them.

The editor has rearranged the record of discussion to keep comments near the papers to which they apply, and has also changed the order of presentation of the contributions to fit a more logical pattern than the exigencies of the Canberra timetable allowed. But he has not attempted to provide an overview of the state of the art, and in the field of galaxy formation more than any other in astronomy (except, perhaps, cosmology) a chapter providing such guidance would be invaluable to readers not already thoroughly familiar with the state of play.

It is no longer very unlikely that non-specialists will take an interest in the areas of study covered by this book, because the high energy astrophysical aspects, in particular, are receiving increasing attention from theoretical physicists who have a background in non-astronomical specialities. But even the congnoscenti have a real problem in distinguishing the wood of a broadly based understanding of how the matter in the Universe got into its present overall state from the many trees of particular theories which explain observations of particular objects or groups of objects without being fitted satisfactorily to the overall pattern.

If you are one of those theorists beavering away on some aspect of the overall problem, then you will find this volume useful not only in providing other models for comparison but in giving some of the observational constraints which must be met by all models. In addition, most active modellers will gain some comfort from the present state of the art; regrettable though it may be to those who treasure the idea of the Universe as a basically simple place, any overview of the work described here must surely lead to the conclusion that both the extreme cases—expansion or outbursts from nuclei, and collapse or condensation of gas clouds—play a part in the real Universe. And there are the various cases of interactions between galaxies to confuse the picture. **John Gribbin**

Organelle by organelle

The Cell in Medical Science. Vol. 1: *The Cell and Its Organelles.* Pp. xiii+366. £7.80; $20.25. Vol. 2. *Cellular Genetics, Development and Cellular Specialization.* Pp. xvii+597. £11.30; $29.25. Edited by F. Beck and J. B. Lloyd. (Academic: London and New York, January 1975.)

THESE are the first two volumes of a four volume series on *The Cell in Medical Science*, which is primarily intended to provide the basis of a cell-science course for advanced biological sciences students and for medical students specialising in cell biology during an elective period or during an intercalated year leading to an honours degree.

Volume 1 is concerned with the generalised cell unit and with the biophysical and biochemical basis of the structure and function of the chief subcellular organelles. Its eight chapters deal with the cell as a unit, membranes and transmembrane transport, the cell surface, the nucleus, cytomembranes and ribosomes, mitochondria and peroxisomes, and subcellular pathology. Though rather poorly illustrated, this volume contains a great deal of useful information and its chapters are mostly well written. That by the editors is a particularly well-balanced treatment of lysosome structure and function and lysosome pathology, pharmacology and toxicology. In my opinion, however, this volume fails to indicate (in spite of promises in the Preface) "the directions in which contemporary cell biology is moving and the methods it uses". This is because, with its traditional, anatomical, organelle-by-organelle approach, little attention is given to the current topics which excite cell biologists —for example, cell fusion and cell hybridisation, cell cooperation, nuclear transplantation, the translation of mammalian mRNA in amphibian oocytes, and the use of cell and organ culture techniques.

The first half of Volume 2 is concerned with cell genetics and development, and begins with four excellent, informative and readable chapters on biochemical genetics, general mammalian cytogenetics, human cytogenetics, and sex chromatin. A very useful chapter on the kinetics of cell production is followed by considerations of cell differentiation, growth and morphogenesis, and ageing. The remainder of Volume 2 comprises comprehensive and, on the whole, well-illustrated chapters on the main cell types and special structures of the neuromuscular system, including the neurone, the synapse, satellite cells of neurones, the skeletal muscle cell, the muscle spindle, and the smooth muscle cell. This theme of morphological adaptation for specific functional purposes will also occupy the whole of Volume 3, in which connective tissues, various endocrine cells, and absorptive and secretory cells will be considered.

In many of the chapters in these first two volumes, medical students would have appreciated more information on cellular aspects of abnormal and disease conditions, at the expense of some of the biochemical, biophysical, physiological and anatomical detail. The balance will to some extent be restored by the publication of Volume 4, which, following chapters on metabolic control mechanisms, will deal with the relationship between the cell and its environment in certain pathological states, including immunological processes, inflammation, wound healing, and carcinogenesis.

The Cell in Medical Science is an essential addition to all medical school and science libraries, where it will be valuable for teachers and research workers, as well as for senior undergraduates.

Michael Balls

Elements of pollution

Chemistry and Pollution. Edited by F. R. Benn and C. A. McAuliffe. Pp. 156. (Macmillan: London and Basingstoke, July 1975.) £8.95.

OVER the past decade there has been much talk of pollution in all its variations, unfortunately in many instances from individuals who were unaware of even the most basic knowledge of the processes involved. This book provides an introduction to the chemistry of the processes of pollution aimed at those individuals with a background of GCE "A" level chemistry; first-year university chemistry in North America. To obtain adequate in-depth coverage the editors have called on eight contributors to write the six chapters.

The stated objective of the text is to provide a factual chemical background to pollution. As might be expected, with eight authors the depth of coverage in each chapter is rather uneven and this is perhaps the most irritating aspect of the book Reference to literature and events outside the UK is rather limited and this might limit its acceptance abroad. The authors recommend the book to universities and colleges for use in environmental pollution courses at the lower undergraduate level. It is adequate for this task. There are no problems set. The book is well produced and has an adequate index.

M. A. Ward

Politics at sea

New Era of Ocean Politics. (*Studies in International Affairs*, No. 22.) By Ann L. Hollick and Robert E. Osgood. Pp.xi+131. (Johns Hopkins University Press: Baltimore and London, April 1975.) £4.40 cloth; £1.40 paper.

THESE studies are confined to US policies and interests in the oceans, the first having particular reference to the Third United Nations Conference on the Law of the Sea and the effect that the different proposals developed there will have for the US. Apart from a little more than one page entitled "International Perspective", however, no attempt has been made to look at the policies from a global standpoint. Having said this, however, it should be remarked that the studies are a very useful contribution to the literature on the Law of the Sea and every participant in the UN Conference should own a copy, or at least have access to one, so as to gain an insight into both the US position in their particular fields and the reasoning behind US statements and activities.

Ann Hollick's study is of greater interest to the marine scientist even though, as is inevitable in a field such as this, it was partially obsolete before it was published, dating from the end of the third (Caracas) session of the Conference in mid-1974; even the outcome of that session is only lightly touched upon. Much, too, has since happened at the recent, fourth session in Geneva.

Consideration of the US position on Marine Pollution and Scientific Research has been confined to some six pages which discuss, first, the reason for including marine pollution within the competence of the conference (this happened because of Canadian insistence after the Manhattan voyage through the North-West Passage in the summer of 1969) and second, how late in the proceedings (summer 1973) the US formulated a policy of Scientific Research; before that, US policy had been almost entirely dominated by petroleum-defence interests. Nonetheless, the US was one of the first countries seriously to consider marine scientific interests at all.

The second study, by Robert Osgood, is an interesting account of US security (that is, military) interests in the oceans, and the surrounding legal implications. This section is of lesser concern to the marine scientist though it does show why US policy has developed as it has, sometimes to the detriment of scientific interests.

The book is well produced and readable in spite of its specialist interest. This is partly a result of a number of fascinating insights into the workings of US government (no doubt others operate in similar fashion but one seldom gets the opportunity to read about them).

Desmond P. D. Scott

obituary

Gordon Hamilton Fairley, a leading authority in the drug treatment of cancer, was killed by a bomb explosion in London on October 23. He was 45.

PROFESSOR Hamilton Fairley began his clinical studies at St Bartholomew's Hospital, London, qualifying in 1954. From 1958–61 he held the Leverhulme Research Scholarship of the Royal College of Physicians During that time he began his research into the immune mechanisms of blood diseases In 1965 he was appointed to the consultant staff at St Bartholomew's, where in 1970 he became director of the Imperial Cancer Research Fund Medical Oncology Unit. He was appointed professor at the unit two years later. Much of his time was spent in work on tumour immunology and in improving drug combinations used in the treatment of leukaemias and related disorders, such as Hodgkin's disease.

As reality replaces grief, the magnitude of the loss of Gordon Hamilton Fairley becomes increasingly clear, and facets of his work, taken for granted, suddenly become irreplaceable. It seems difficult to realise that only a decade has elapsed since Gordon directed his attentions to a new approach to cancer research. Following his sound clinical training in oncology, gained under Sir Ronald Bodley Scott, he chose to develop a close liaison with pure scientists to develop a rationale for future clinical studies. During this period he became a close friend of Peter Alexander, a scientist without clinical training, and between them they taught each other much of their respective disciplines. Basic scientific observations were rapidly reported, particularly in tumour immunology, and tested in clinical programmes. One of his major contributions was to lay down rigid principles concerning these clinical programmes, particularly the concentration of efforts into only a few diseases at any one time, and the use of carefully controlled randomised clinical trials He had the remarkable knack of keeping the programmes relevant, while keeping an open mind for scientific developments that were important. Using these principles his contribution to the fields of leukaemias and lymphomas was considerable He had the ability to be effective without making enemies, because of a personality and charm with a common purpose, without intertive smile could shorten committee meetings by hours. It meant that a unit was created which was bound together with a common purpose, without internal squabbles; and his generosity to those who worked for him instilled into them a quality they passed on to others He was responsible for training half the medical oncologists at present practising in Britain, and his monument will be the living contribution yet to be made by these people. All these qualities made Gordon an obvious choice to steer the direction in which medical oncology takes in Britain. Because he was so young, in this he is irreplaceable. With his death we lose the founder of British medical oncology, but more tragically to many of us we lose a dear friend.

Ray Powles

B. A. Southgate, CBE, a leading British researcher in problems of water pollution, has died at the age of 71.

Shortly after leaving Cambridge, he joined the recently formed Water Pollution Research Organisation (part of the former Department of Scientific and Industrial Research) as a member —and ultimately leader—of a team investigating the effects of pollution on the Tees estuary Subsequently, many other such surveys were carried out under his direction, the most important of which was that concerned with the Thames estuary. A predictive mathematical model was developed to establish the best way of improving conditions in the estuary. This research was to form the basis of a new kind of approach to river management. At the outbreak of World War II, Dr Southgate set up the first permanent Water Pollution Research Laboratory (WPRL) in the UK at Watford and was appointed director in 1943. In 1948 he published *Treatment and Disposal of Industrial Wastewaters,* for many years one of the standard reference works. He was awarded a CBE in 1954, the year in which his laboratory moved to Stevenage. After retiring from WPRL in 1966 he continued to act as a consultant to relevant organisations in the UK and in the United Nations.

announcements

Appointments

D. A. Hamburg has been appointed president of the Institute of Medicine, Washington, D.C.

The new pro-vice-chancellor of the City University, London is to be **J. C. Levy.**

E. C. Melby, Jr., has been appointed chairman of the Institute of Laboratory Animal Resources of the National Research Council in Washington, D.C.

Award

The Gairdner Foundation of Ontario has presented one of its 1975 awards to **H. E. Huxley** in recognition of his outstanding contribution to our understanding of the molecular basis of muscle contraction.

Miscellaneous

A workshop on **biological surveys of estuaries** is to be held at UWIST, Cardiff, UK from January 5–9, 1976 A limited number of workshop places are available for river biologists For further details apply to:—Technical Presentation Manager, Water Research Centre, Stevenage Laboratory, Elder Way, Stevenage, Herts, SG1 1TH, UK.

Scientific visits to the Soviet Union, Czechoslovakia, Hungary, Romania and Bulgaria. Cultural agreements with the above countries provide for short visits (two weeks) and medium term research visits (two to six months) for British scientists. Scholarships are also available for periods of up to one year. For full details apply to:—Higher Education and Science Department, The British Council, 10 Spring Gardens, London SW1A 2BN.

Person to Person

London-Washington. Family house (three young children) sought in Bethesda (NIH)–Washington area for 3 months in exchange for three-bedroom North London house (Dr David Brown, Department of Pharmacology, The School of Pharmacy, London University, 29/39 Brunswick Square, London WC1N 1AX, UK; (01-837 7651 ext. 55).

London—South Carolina. Two- or three-bedroom house wanted in London area for professor on sabbatical from May until December 1976 in exchange for four-bedroom house near South Carolina University. Car may be included (Professor J. L. Safko, Department of Physics, University of South Carolina, Columbia, S.C. 29208, USA).

Eggshell thinning in Falco. Eggshell thinning of several species of raptoral birds has been demonstrated in the British Isles and North America. Drs David Peakall and Lloyd Kiff are attempting to document this change on a global scale. They would be interested to know the whereabouts of any post-1945 eggs of *Falco peregrinus*, *F. biarmicus*, *F. jugger* and *F. cherrug*. The only exception is *F. peregrinus* collected in the British Isles. The measurements required—length, breadth and weight—can be obtained easily without damage to the specimen. They would be grateful if anyone knowing the location of these eggs would write to them (David B. Peakall, Canadian Wildlife Service, Department of the Environment, Ottawa, Ontario K1A OH3, Canada, or Lloyd F. Kiff, Western Foundation of Vertebrate Zoology, 1100 Glendon Avenue, Los Angeles, California 90024, USA).

Human zygotes. Information is required on a hypothesis on the sex of human zygotes. For this purpose will anyone with data on the sex of any monoamniotic twin pairs please communicate with Dr W. James, Galton Laboratory, University College, London, UK

There will be no charge for this service. Send items (not more than *60 words*) to Holly Connell at the London office. The section will include exchanges of accommodation, personal *announcements* and scientific queries We reserve the right to decline material submitted No commercial transactions.

November 20, 1975

Questioning the quinquennium

THE practice whereby British universities are financed on a quinquennial basis is the root of many of their present problems. In fact, the question now seems to be not so much if, but when, that system will be done away with or modified out of all recognition. The problem is that the arrangements for correcting (for higher-than-expected inflation rates) a particular year's expenditure—planned at the beginning of the five-year period—is cumbersome and drawn out. One of the universities' most immediate complaints, for example, is that their grant for the next academic year, 1976–77, is not yet fixed even though they are already admitting students for courses starting next October and have therefore had to make some fairly detailed plans. One suspects that even the government's much-touted but tentative ideas for introducing cash limits on public expenditure, with no *post facto* corrections for 'extra' inflation, would be welcome, relatively speaking, because at least the universities would then know where they stood.

An added complication, of course, is that the whole business of salaries for university academics is in disarray. Figures put out recently by the Department of Education and Science show how they have altered, at 1970 prices, over the past five years. The lecturer scale has just about kept up with inflation, and the recent Board of Arbitration settlement means that lecturers' salaries as of October 1974 (which is as far as the negotiations have got!) are some 20% ahead of 1970 in real terms. But senior lecturers and professors, who can hardly be said to earn astronomical salaries, had until the recent settlement fallen seriously behind.

The average professorial salary in 1970 was £5,610, whereas by 1974 it had shrunk a startling 12% to £4,920 at 1970 prices. The level for that year was effectively increased to £5,905 (1970 prices) by the recent settlement. This only put professors about 5% ahead in real terms, and that has been more than eroded in the past year.

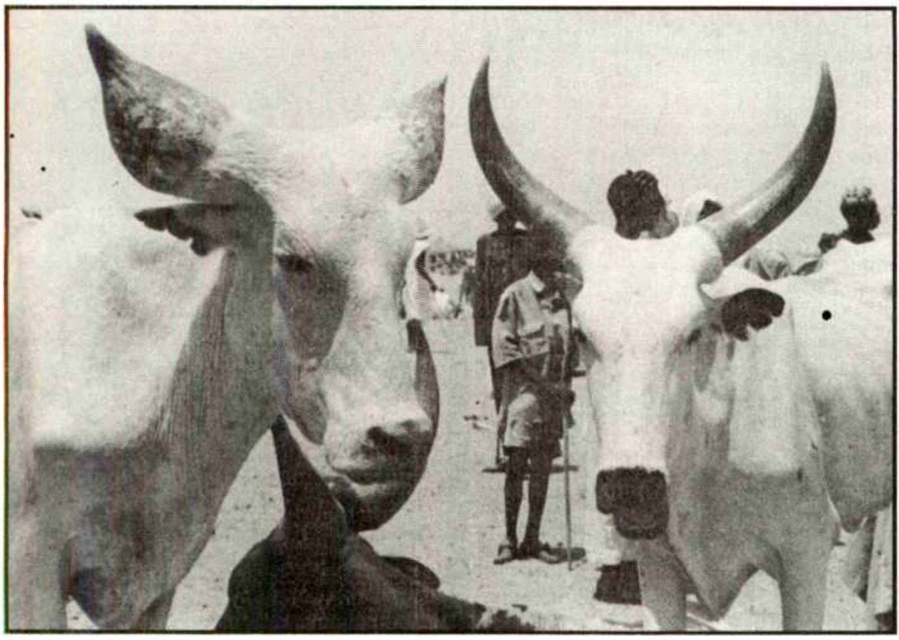
Planning anything is difficult for everyone, including the Department of Education and Science. Bearing in mind that academic salaries account for some 50% of university non-capital expenditure, planning is even more difficult when it comes to universities. But is it an excuse for inaction?

Where have all the teachers gone?

THE shortage of science teachers in British schools seems likely to intensify, with a consequent loss of potential scientists and engineers. This gloomy prognostication emerged recently when educationalists from varied backgrounds gathered at the Royal Society in London to consider problems in the teaching of science and mathematics. The meeting also demonstrated the apparent gap between the aims of many school teachers and the knowledge and attitudes required of first-year students at colleges and universities.

The shortage of scientists and mathematicians in schools, which exists in spite of the overall national sufficiency of teachers, will be exacerbated by the cuts in the numbers and sizes of teacher training colleges, recently necessitated by instructions from the Department of Education and Science. Where small departments within colleges have to be closed down they may well include those concerned with science, so that even fewer primary and secondary school teachers will be available with the backgrond necessary to teach science effectively. Another disturbing factor will be the loss of flexibility in training colleges which are amalgamated with polytechnics and adopt courses leading to the BEd degree of the Council for National Academic Awards. These courses will require students to choose their main subject from the outset, rather than specialising only after a broad, basic course including mathematics and science. During a wide ranging basic course students can be persuaded, by imaginative teaching methods, that science is not necessarily boring, rigid and too difficult, as they may have thought at school. In these circumstances students might opt to specialise in science or mathematics after the first few terms, but when the choice has to be made at the beginning of the first year the chances are that prejudices acquired at school will have an undue influence.

School teachers who are trying hard to arouse enthusiasm for science and mathematics among their pupils, through the use of new methods and curricula, are apparently coming into conflict to some extent with the needs of colleges and universities. The contributions of academics to the meeting at the Royal Society suggested that students who have learned about theories and concepts at an early age do not all have sufficient factual knowledge when they embark on higher scientific education. It is more important, the academics say, to understand the meaning of *p*H than to be familiar with molecular orbital theory. But the school teachers counter that they have to interest their pupils in science, and this is not necessarily done by constant learning of facts. The teachers ask whether they are supposed to be preparing pupils to enter higher education or to become effective citizens. This is a question that will have to be considered carefully in future deliberations about the structure and content of British education.



Kuri cattle at Grédaya market, Chad

Conserving genetic resources

Many breeds of livestock and innumerable varieties of crops which have arisen in the course of man's agricultural history are now in grave danger of being supplanted by the comparatively fewer highly-bred animals and plants of modern agriculture. A priceless and irreplaceable reservoir of genetic raw material is threatened. Peter Collins looks at efforts now underway to preserve some of the rapidly vanishing breeds of livestock. Next week Eleanor Lawrence reviews international efforts to conserve crop genetic resources.

CONCERN for the fate of traditional breeds of livestock is an aspect of conservation that has as yet received little attention at the international level. It is true that cerain breeds, especially of cattle, that would otherwise have disappeared have been preserved by societies set up for this specific purpose. But most breed societies are at least as much concerned with the quality and performance characteristics of the breeds they represent as with conserving them as sources of genetic material. This is by contrast with the tremendous interest now apparent, and actively fostered over many years by the Food and Agriculture Organisation (FAO), in maintaining genetic stocks of crop plants.

Until fairly recently the specialised breed society was largely a British institution. Although this movement is now spreading, breed societies are still confined principally to the agriculturally more advanced countries, but even they have not prevented the disappearance of a number of ancient and potentially valuable breeds. Nowhere outside the UK is there anything approaching the Rare Breeds Survival Trust, a body specifically concerned with the conservation of British breeds of livestock that would otherwise become extinct.

Pure stocks of major commercial breeds have, of course, been maintained, especially where their performance is particularly in line with present thinking in the agro-economic field. But the number of such breeds has been declining for many years, and this process is accelerating rapidly. Thus, a recent FAO publication (*Report of a Pilot Study by FAO and UNEP on Conservation of Animal Genetic Resources,* Rome, March 1975) identifies 118 breeds of cattle in Europe and the Mediterranean Basin as being "in a relic state, in danger now, or in danger in the future." It records only 30 native breeds from the same group of countries as "not in danger".

Among those already threatened with extinction are such familiar breeds as the Irish Kerry ("already in a relic state"), and the Red Poll and Beef and Dairy Shorthorns in the UK; even Scotland's Ayrshire is in danger of disappearing. The decline is particularly marked in the dairy breeds, as it is throughout Europe, on account of the tremendous rise in popularity of various types of Friesian. There has always been a certain amount of deliberate cross breeding in the livestock industry, relying on the maintenance of purebred stocks of the selected parent breeds. This aspect of conservation has scarcely been recognised, mainly because the objective has been increased performance and production of more and better meat and milk, and occasionally, disease resistance.

But it is this point of view that has, for very good reasons, principally influenced the FAO's approach to the problems of increasing livestock production in the developing countries. Thus, the FAO has frequently advocated the use of local breeds in these countries for crossing with introduced animals, but has not been greatly interested in the conservation of other, less immediately useful indigenous breeds. Now, there is increasing concern that the success of such introductions is beginning to erode the irreplaceable genetic resource that exists in traditional native African and Asian breeds. Many of these, it is feared, may disappear before there has been a chance to evaluate their performance under improved conditions, or for cross breeding with other local or introduced breeds.

With the sudden surge of interest in conservation, and more particularly, with the creation of the United Nations Environment Programme (UNEP), this situation has begun to change. UNEP has a specific objective in this field, based on a resolution of the Stockholm Environment Conference of 1972. This is "to initiate the preparation of a comprehensive catalogue of threatened species and varieties of crop plants, fish, domestic animals and micro-organisms, and to cooperate with the FAO in its programme for genetic resource conservation . . ."

Earlier this year the FAO and UNEP published a report of their first joint project. The project—in effect, the first international step towards the conservation of genetic resources of domestic animals—has two objectives. First, "to prepare a preliminary list of breeds of farm animals which are in danger of extinction together with an account of any measures which have been recommended or taken to prevent this extinction"; and, second, an examination of the problems involved in the conservation of a single breed in a developing country.

A breed of humpless cattle known as the Kuri was chosen for the second part of the project. The Kuri, whose habitat is the islands and shores of Lake Chad, is unique in the possession of inflated, spongy horns, apparently (though exactly how is not known) an adaptation to its habits and habitat. A fine swimmer, the Kuri actually feeds in Lake Chad, eating the coarse forage of the shallow shores, and swims to and fro to reach new pastures. The concern about the survival of the Kuri, however, is based on a series of circumstances affecting, or liable to affect, many other breeds in developing countries.

Since 1960, a rise in the water level of Lake Chad seems seriously to have reduced the available grazing area. Then, because of the demand for Kuri stock, which are described as moderate milkers and excellent beef animals, local farmers could obtain two zebu cattle for one Kuri. This cannot be avoided where numbers of cattle rather than quality is still important to local tribes, but the consequence is dilution of the Kuri herds with zebu blood. In addition, the Sahelian drought of recent years has led to pressure on the Kuri grazing areas by zebu herds from the Sahel.

The original project for the conservation of the Kuri was proposed in 1972 by the Lake Chad Basin Commission. The aim is to establish several herds of pure-bred Kuri, selected with an emphasis on the animals' economic qualities, but including one small herd specifically intended to preserve the unique, inflated, buoy-shaped horns which have attracted many travellers in the Lake Chad region—and which could make these Kuri a tourist attraction in themselves. In its latest form, with UNEP–FAO assistance, this project can be seen as a valuable exercise in the deliberate conservation of a threatened breed.

While most attention has so far been directed towards cattle, the situation is little different where other farm livestock are concerned. Many breeds of sheep, pigs, horses and even goats are in danger of becoming extinct, mainly for the same reasons: changes in the pattern of farming, improvement of land, and the constant demand for higher production based on the use of feeds not available in the 'natural' environment. Other domesticated animals, such as the camel and its South American relatives, have scarcely been considered from the conservation point of view; a minor species such as the donkey could well disappear simply because no one has thought of doing anything to prevent this happening.

In general, there are three aspects of this conservation problem: cultural, scientific and economic. The traditional breeds of livestock are, first of all, as much a part of our cultural heritage as are ancient buildings and works of art. From the scientific point of view, certain breeds have colour genes. The larger species, too, are useful as controllable sources of milk, blood and various tissues of particular genetic interest.

But it is the practical economic argument that is the most important. The classic example of this is probably the "discovery" by American poultry breeders of the traditional Cornish breed, reduced in its home country to a purely fancy bird. Crossed with other breeds, it made possible the rapid growth on which the modern broiler industry depends.

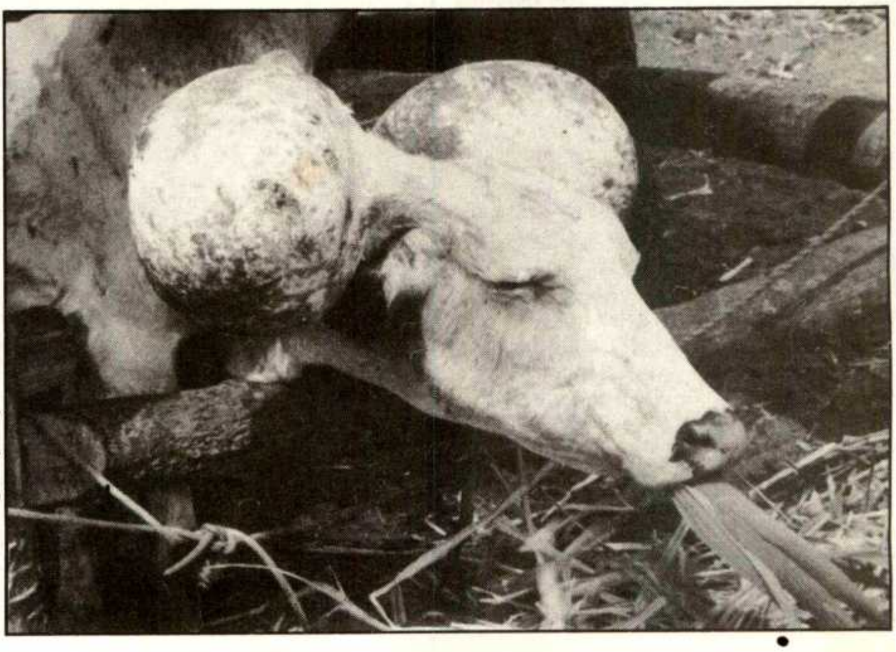
Similarly, remote breeds of sheep, for example from Greece and Finland, were unknown beyond their own homelands until, because they were highly prolific, they were seen to be suited to modern husbandry techniques. There are several very prolific tropical breeds of sheep, too, in the Caribbean, in Latin America, West Africa and South-east Asia, that could also be useful.

An even more important example is probably that of the 'trypanotolerant' indigenous cattle of various West African countries. If these could be successfully crossed, or developed under improved conditions to provide a more economic yield of meat and milk, it might be possible to avoid the enormous cost of controlling tsetse fly, the vector of trypanosomiasis, which denies thousands of square miles of Africa to the livestock industry.

One apparent problem, however, is the lack of knowledge of the characteristics of most of the indigenous breeds of the developing countries. A first step, which must come before a conservation programme can be set up for any breed, is obviously its evaluation in terms of production, disease resistance, and potential when crossed with other, better known breeds. This means a long and enormously costly series of projects.

Moreover, even where there have been apparently successful cross-breeding programmes, little is sometimes known about what is happening from the genetic point of view. Thus, it was long considered that the "hybrid vigour" (heterosis) apparent when certain exotic, highly developed breeds have been crossed with local stock, was due to the introduced, often larger animal. Now it seems that this is not necessarily the case, and it is essential that sufficient pure-bred herds of the local breed be maintained if such cross breeding is to be continually successful. An example is quoted of the local Criollo cattle in South America, which have been successfully crossed with Brahman (zebu) bulls from the United States. Now the Criollo themselves are in danger of dying out, and the genetic resource they represent could be lost.

Conservation of livestock breeds for economic or cross-breeding purposes demands the maintenance of considerable herds of pure-bred stock, which many of the poorer developing countries may not be able to afford. This therefore is a case for international action. Where a breed is being maintained for scientific purposes, smaller herds, such as might be kept in rare animal parks or large zoos such as Whipsnade, will suffice. Where the interest is solely cultural or historic, such as in the case of the UK's White Park cattle at Cadzow and Chillingham, even fewer beasts need be kept and the problem of cost may be less important than that of management. Certainly, some of the hundreds of breeds of livestock now kept on the world's farmlands will disappear. But with the new approaches to agriculture, and the call to combine higher production with better use of animal and plant resources, everything must be done to ensure that as little as possible of the genetic heritage available in these breeds is lost. ☐



Kuri cow showing buoy-shaped horns

Relative deprivation of Civil Service scientists

SENSIBLE negotiators will use the breathing space provided by the British Government's £6-a-week pay policy to seek solutions to their long standing industrial relations problems. One such problem is that of the pay and careers of Civil Service scientists, including those employed in research councils, the UK Atomic Energy Authority and other closely related areas of employment.

Civil Service scientists are highly discontented. They have become more frustrated since the hopes raised by the Fulton Report on the Civil Service that equal opportunities would be given to specialist staffs have been seen to come to naught. It is difficult to recall a time in the past 30 years when they have so resented the comparative injustices which they suffer.

Why should this be so? The best point at which to begin is with the recruitment of staff. The Civil Service recruits graduates with a First or Upper Second Class Honours degree—and, perhaps, a second degree—separately to the two main groups, Administration and Science. Although in both cases recruits will meet the academic requirements, there is very little doubt that in practice the scientist will be the more highly qualified.

After a year or two of service the administrator, at every grade level he reaches below £12,000, at which point there is unified grading, will be paid more than his science counterpart. The difference is of the order of 3.5–5.5% at comparable salary maxima. The relationship is similar in respect of A-level entrants to each of the groups.

But this is far from the whole story. The salary differences—themselves impossible to justify and a constant source of irritation—are aggravated further by the fact that career progression in administration is greatly superior to that in science. Consider the example of the high quality graduate, with a First or Upper Second Class Honours degree. The scientist will get to Higher Scientific Officer in his late 20s (only 2.3% are under age 25), to Senior Scientific Officer in his 30s (8.6% under age 30) and to Principal Scientific Officer (£7,205) in his late 30s (0.7% under age 30). A handful will get there more quickly.

Compare this with the high quality graduate administrator. He will become a Principal (£7,450) between the ages of 28 and 32. It is hardly surprising that he gets there more quickly than most scientists. There is an additional grade (SSO) in the science structure. The administrator will, as a matter of virtual certainty, progress to Assistant Secretary (£11,000) in his early 40s.

Thus the high quality graduate administrator can normally expect to progress to a salary level some £4,000 above that of the scientist. The ratios of promotions above Assistant Secretary (£11,000) for the administrator are broadly similar to those for the Principal Scientific Officer (£7,205) on the science side but, of course, at each stage at one step higher.

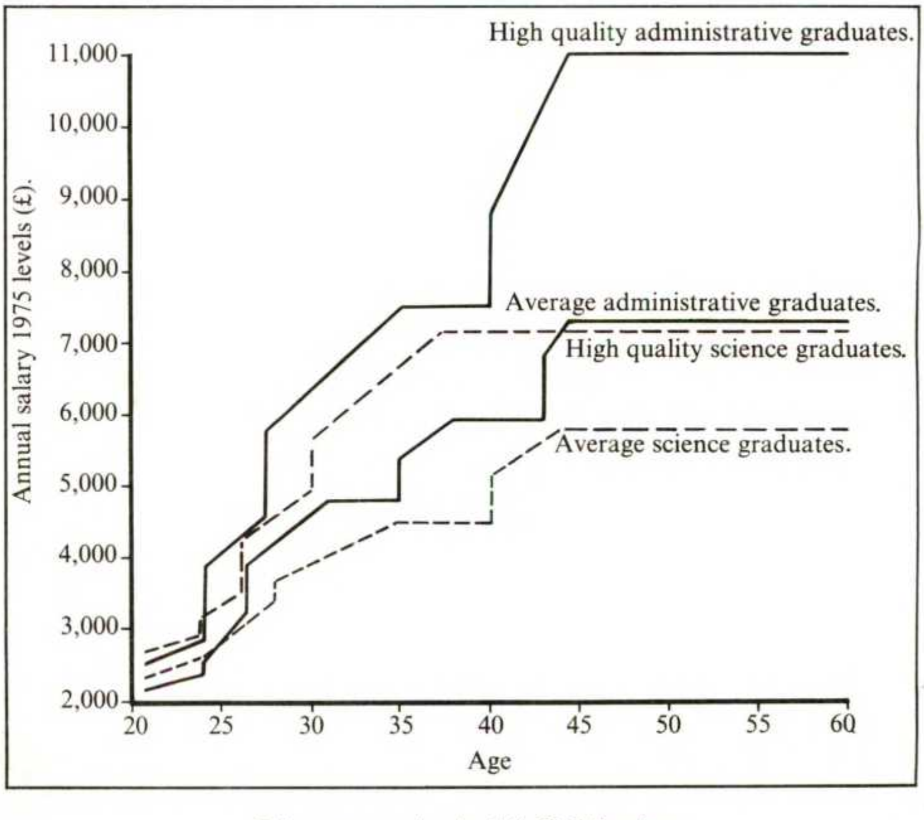
The career earnings of the administrator are thus very much more than those of the scientist, as the pattern illustrates. For the situation in which neither the administrator nor the scientist progresses further than indicated—and the chances of doing so are marginally greater for the administrator—a comparison of their career earnings between the ages of 21 and 60 shows that the best administrator will receive 34% more than the scientist. A comparison for average staff shows the administrator with a 24% advantage.

In 1974 there were 1,100 vacancies for science graduates in the Civil Service proper. Posts were offered to 1,415 applicants, but only 661 actually took them up. It is very unlikely that lack of job interest or of good facilities for research were the explanation for this. There can be no doubt that pay and career prospects played a major part in the decision making. In fact, scientists would all be better off financially if they entered the Civil Service as administrators.

Yet, odd as it may seem, very real obstacles are placed in the way of scientists who wish to transfer, later in life, to administration, in spite of the good intentions of the Civil Service Department. In this the Civil Service differs from industry which draws heavily on scientists to fill posts at large.

Civil Service scientists are not obsessed with jealousy of administrators. They do not at all begrudge administrators what they have. But scientists do not see themselves as in any way inferior. They consider that the intellectual contribution of the scientist is worth at least as much by way of pay and career prospects as the contribution of the administrator. They ask no more than that there should be equality of opportunity for all Service recruits of equal ability. Could not all of us agree about that as a reasonable objective? As things are at present scientists are not even in the same race as administrators.

Cyril Cooper



Salary expectation in UK Civil Service

international news

Busting the FDA

by Colin Norman, Washington

A MAJOR debate is shaping up in the United States over the manner in which new drugs are developed, tested and marketed. Although the issues are hardly novel and the arguments are likely to be shrill, the debate could eventually result in the first sweeping changes in food and drug laws since drug regulations were tightened in 1962 following the thalidomide disaster in Europe.

The focus of the debate will be a bill, drafted by Senator Edward M. Kennedy, which seeks to dismantle the Food and Drug Administration (FDA) and to strengthen and streamline the process by which new drugs are tested and approved. Although the bill has not yet been formally introduced into the Senate, it is already generating considerable discussion.

The impetus behind the bill comes from a series of highly publicised hearings, conducted over the past couple of years by Kennedy's health subcommittee and by a subcommittee on Monopoly headed by Senator Gaylord Nelson, during which the FDA has been flayed from all sides.

On the one hand, a number of scandalous practices in the sale, promotion and testing of drugs have been unearthed, and the FDA has been accused of sloppy, ineffective and even biased regulation of the drug industry. In short, it has been alleged that the American public is being bilked and its health endangered by unsafe and ineffective drugs which have been allowed on the market with inadequate testing and review. The drug industry, which was once widely admired and respected for its contributions to public health has—in some cases deservedly—become an increasingly plump target for criticism.

But, on the other hand, a phalanx of economists, pharmacologists and physicians has argued that the American public is being short-changed for an entirely different reason : the drug laws are now so strict, and the approval process for new drugs is so tortuous, that innovation is being stifled and patients are being denied valuable drugs which are available in other countries, especially Europe.

Whatever the validity of the various charges, it is clear that some changes in drug laws will have to be made. As Mr Kennedy, whose chairmanship of the health subcommittee gives him a pivotal role in such matters, put it during a recent symposium at Tulane University, "there are fundamental defects in our nation's regulatory procedures for prescription drugs, and these defects can no longer be ignored".

Kennedy's bill attempts to bring about a variety of improvements in the situation by breaking up the FDA and replacing it with two separate agencies —a Drug and Devices Administration and a Food and Cosmetics Administration. It also seeks to strengthen the scientific competence of the staff which reviews applications to test and market new drugs; improve and, in some cases, shorten the review process; and establish a system for monitoring clinical experience with new drugs.

The 1962, post-thalidomide amendments to the food and drug laws established a testing procedure which must be followed before any new drug can be marketed in the United States. The goal of the process, which is monitored and licensed by the FDA, is twofold: to determine that drugs meet safety requirements, and to demonstrate that they are effective. The tests, in short, proceed from animal experiments, through limited toxicological tests on humans—usually prisoners—to broader clinical trials to determine effectiveness. The procedure is rigorous and expensive.

Criticis of the system who claim that the regulatory filter allows dangerous and ineffective drugs to slip through generally tend to blame the administration of the laws rather than the laws themselves for endangering the health and wallets of the American public. Their central allegation is that the FDA is so heavily dominated by industry pressure that its decisions are frequently biased in the industry's favour. As evidence, they cite the 'revolving door' syndrome in which top FDA personnel are often drawn from the drug industry and usually return to it. And scarcely a month goes by without a Congressional committee hearing evidence that some drug or another is unsafe or useless.

Moreover, the air of public mistrust which hangs over the drug industry doesn't help the industry. The mistrust is understandable, in view of a string of allegations which have been voiced at the Senate hearings and in various reports and studies.

To take just a couple. Last year, four former drug salesmen told Kennedy's subcommittee in considerable detail of the scandalous gimmicks and hard selling tactics which they used in peddling their wares to prescribing physicians. The tactics ranged from perusing the files of pharmacies to see which physicians were prescribing their company's drugs, to the industry's practice of sending 2,000 million free samples through the mail to physicians each year. And recently, wide publicity has been given to a study, supported by Consumers' Union, which has unearthed a number of instances of drugs which are considered dangerous or ineffective in the United States, being marketed by multinational companies, with limited controls, in Latin American and Carribbean Countries.

But the critics' most widely publicised piece of evidence of alleged industry favouritism within the FDA cropped up in August last year, when 10 present and former employees of the agency testified to Kennedy's subcommittee that they had been harrassed or transferred, or that their decisions had been countermanded, when they took action against some drugs. Those allegations immediately brought promises from the Department of Health, Education and Welfare, FDA's parent department, that a thorough investigation of the matter would be conducted. A seven-member panel was eventually established, under the chairmanship of Dr Thomas Chalmers, Dean of the Mount Sinai School of Medicine, to look into the charges. And the FDA also began its own investigation.

The FDA exonerated itself in a massive, 906-page report on the charges last week, but its conclusions were, understandably, not immediately accepted by the critics. The Chalmers committee is expected to complete its investigation early next year, and its report will clearly play a substantial role in the debate on Kennedy's bill.

As for the allegations that the drug laws are so strict that they are stunting the development of new drugs and depriving patients of valuable products, those charges were first seriously raised in 1972 by economist Sam Peltzman of the University of Chicago, and they have since been extended by William Wardell and Louis Lasagna, both of whom are pharmacologists at the University of Rochester. Their studies have recently been published by the American Enterprise Institute, a conservative Washington 'think tank'.

Peltzman examined the rate of introduction of new drugs in the United States before and after the 1962 amendments to the drug laws, and compared his findings with experience overseas. He found that innovation was markedly reduced by the amendments, and he concluded that the net cost to consumers of the delayed introduction or non-availability of new drugs amounts to about $250–$350 million a year, over and above any benefits derived from the regulations.

Wardell and Lasagna compared the availability of drugs in the United States with the situation in Britain, where efficacy requirements are not as rigorously enforced, and they concluded that valuable new drugs are marketed more quickly in Britain, and that some drugs widely used in Britain are still not available in the United States.

The FDA's most vigorous and elegant rebuttal of the Peltzman–Wardell–Lasagna thesis was made in 1973 by Dr Henry Simmons, then Director of FDA's Bureau of Drugs, in testimony before Senator Nelson's subcommittee. Citing studies conducted for the FDA by the National Academy of Sciences, Simmons pointed out that of 4,300 drugs marketed before the 1962 amendments came into effect, only 40% showed substantial evidence of effectiveness. He also accused doctors of over-prescribing drugs, and said that adverse reaction to drugs has now developed into a major health problem. It was precisely because of such factors that the 1962 amendments were passed. Simmons also suggested that the FDA has serious reservations about the safety of some drugs that are available abroad, and he cited the lack of any thalidomide-like tragedy in the United States as evidence of the effectiveness of the drug laws.

Senator Edward Kennedy

Kennedy seems to have come to the conclusion that there is more than a grain of truth in the criticisms of both sides. In his speech at Tulane University, he acknowledged that the FDA has some serious problems, but he suggested that they stem from the agency's "incredible range of unrelated responsibilities, and its insufficient scientific expertise". That explains why his bill would cleave the agency into two separate units, each of which would have more manageable responsibilities.

As for the scientific quality of FDA's staff, a host of investigations of the agency carried out over the past decade or so have almost unanimously suggested that the quality needs to be improved. That conclusion is hardly surprising. Because the Bureau of Drugs is spread over six different buildings in Washington alone, there is little opportunity for FDA officials to do research of their own and, as FDA Commissioner Alexander Schmidt recently put it, "opportunities for professional growth are meagre". Kennedy's bill would therefore beef up the quality of the scientific staff by reserving a number of positions for academic pharmacologists to serve in the agency for two or three years, with ample research time and equipment to carry out their own research.

There is, however, at least one aspect of drug regulation in the United States on which most people agree: once a drug is approved and marketed, there is very little follow-up to monitor for unexpected side-effects, or for possible new applications. As Kennedy suggested last week, "the absurdity of the system is staggering. We clear a drug for a particular use. We are meticulous about requiring proof of effectiveness for that use. We spend millions of dollars and years of time developing that proof. But once a drug is finally approved, it is turned loose, free from all controls and follow-up".

FDA does run a system for receiving reports of adverse drug reactions, but a recent report by the Congressional General Accounting Office found the system to be hopelessly inefficient, and even Mr Schmidt acknowledges that "the greatest single weakness of our present regulatory system is the abysmal reporting by almost all professionals of their drug experience—good, bad or indifferent".

Kennedy's bill seeks to take care of those complaints by changing the regulatory process in such a way that some drugs could be more closely monitored and others will be brought more quickly into use. He has proposed that before some drugs are given full commercial approval, they should be placed on a limited distribution to a few hospitals, or to a particular region of the country, and their use should be closely watched. The proposal would allow drugs which may have potential problems to be closely monitored, and it would also enable products which seem especially promising, and whose safety has been reliably determined, to be brought more quickly into use—limited distribution could be substituted for some of the time-consuming and costly testing for effectiveness.

Mr Schmidt said, also in a speech at Tulane University earlier this month, that the proposal "might permit earlier appearance in the United States of many drugs, in return for a longer investigational phase controlled by FDA. This seems to me a reasonable trade-off". And Dr Wardell said in a telephone interview last week that he believes the proposal has some merit, provided that limited distribution and monitoring of new drugs is not simply added to the already lengthy review process.

As for the suggestion that FDA should be split in two, Mr Schmidt declared himself opposed. The regulation of food and cosmetics, he said, is similar to the regulation of drugs and medical devices, and the two functions can effectively share a central legal and enforcement division. Nevertheless, he acknowledged that "when Senator Kennedy suggests changes in FDA's structure, we are inclined to pay attention".

Kennedy has promised to send his bill to interested parties as soon as it is formally introduced in the Senate, and he will conduct hearings on it next spring. With Congress and the White House both battened down for the elections by then, it is unlikely that the measure will be passed before the end of the year. But the bill will very probably form the basis for legislation in the not too distant future.

● To help pave the way for the science policy office which will soon be re-established in the White House, President Ford has established two top-level committees of scientists to advise the Administration on a number of important science policy issues. One, chaired by Dr Simon Ramo, will "examine issues and opportunities involving the fostering economic strength and in improved utilisation of technology in assuring that economic goals are achieved along with environmental goals", according to a White House announcement. The other, chaired by Dr William O. Baker, will "consider developments that may take place in science and engineering in the decade ahead and examine the national policy implications of these developments". Members of both committees are distinguished and well-versed in Washington science advisory activities. ☐

Soviet scene

from Vera Rich, London

THE former President of the Soviet Academy of Sciences, Mstislav V. Keldysh, who retired from his post earlier this year on the grounds of ill-health, seems to have made a recovery, judging from recent articles in the Soviet press. On November 8, the day following the announcement of this year's State Prizes, it was he, and not his successor Academician Vladimir A. Kotel'nikov, who gave the traditional appreciation of the achievements being honoured. A few days later, on November 16, he was again featured in *Pravda,* in an extensive interview on the success of the recent Venera 9 and 10 probes.

Neither of the articles is in any way out of context. Keldysh is still Chairman of the Lenin and State Prize Committee for Science and Technology, and was closely involved with the Soviet space programme in its early days. Nevertheless, those who suspected some connection between Keldysh's retirement and the postponement of the Academy's Jubilee Celebrations from May 1974 to October 1975 will doubtless find something more than fortuitous in his sudden reappearance in print so soon after the conclusion of the celebrations.

One interesting feature of this year's State Prize lists is the emphasis given not only to basic research and applied technology, but also to the production of text books. Although in the past Lenin or State Prizes have been awarded to authors in connection with a specific scientific monograph, this year three works intended for students' use have been specifically honoured. They represent a broad spectrum: ordinary differential equations, general surgery, and radio receivers.

The Soviet academic system makes a sharp division between pedagogic and research activities—the universities confine themselves entirely to teaching, while original research is carried out only in special institutes. Although a research scientist will frequently hold more than one post, combining research at an appropriate institute with university lectures, his main chance of official recognition in the State and Lenin Prize lists has until now been through his research.

This new emphasis on the importance of text books is an interesting sidelight on the growing concern of Soviet educationalists who want works of "a high scientific and methodological level" at their disposal for use in universities and colleges of special secondary education.

- Following the recent press campaign against Academician Andrei D. Sakharov, the announcement that the Soviet government would not permit him to travel to Oslo to receive the Nobel Peace Prize came as no surprise. Nevertheless, the reason given—that he is in possession of classified information—demands some scrutiny. It is more than seven years since Sakharov lost his security clearance, which raises the question of whether any information to which he previously had access is still on the secret list.

Moreover, in 1958, the year that Boris Pasternak decided to decline the Nobel Prize for Literature after a prolonged press campaign against him, the award of the Physics Prize to Cherenkov, Frank and Tamm was hailed as a notable tribute to Soviet science, and the three winners received the necessary visas for Stockholm. This was in spite of the potentially sensitive nature of their work: Tamm and Sakharov had actually been working together on certain aspects of thermonuclear reactions.

The Soviet authorities apparently find Sakharov's prize an embarrassment, and for reasons of policy would prefer that he should not receive the award in person. If the precedent is followed in the future, however, a Soviet winner of the Physics Prize might well be forced to receive it *in absentia.*

- Increased concern is being felt for the fate of Andrei N. Tverdokhlebov, the physicist who was arrested on April 18 in connection with his attempts to establish a Moscow group of Amnesty International, and who is now being held in the Lefortovo prison in Moscow. The link between physics and concern for human rights and freedom dates back to Stalin's time, when the need for a nuclear arsenal allowed physicists to speak from a relatively privileged position and to avert a Lysenko-style disaster in the physical sciences. Tverdokhlebov has been closely associated with Academician Sakharov, whose "Human Rights Group" he joined as a founder member, and also with Valentin Turchin, who was a co-signatory of the second Sakharov manifesto of 1970. An appeal by Turchin on behalf of Tverdokhlebov has been sent to the West. According to press agency reports, Tverdokhlebov and another member of the Amnesty group, the Ukrainian science-fiction writer Mykola Rudenko, will be charged with "anti-Soviet slander", but it is not yet clear whether formal charges have been made.

- Two significant developments in the field of automation have been announced recently in the Latvian SSR. The first, described at the First All Union Conference on Biomechanics in Riga, is a proposed walking robot for rough terrain. Although this has been mooted several times in the last few years, the new version, designed on the basis of extensive mathematical simulation, seems to have been produced with far greater attention to practical implementation than some of the rather theoretical proposals so far discussed. The latest ideas include lasers as a possible means of stimulating vision, and the automatic selection of the form of motion —velocity, length and height of steps —to fit the demands of the terrain. A six-legged robot is likely to prove the most manoeuvrable.

The second and perhaps more alarming development concerns the management-control automation system recently introduced into the radio industry in Latvia. According to the *Novosti* agency, this system, based on a Minsk 22 computer, is intended to assess the competence of production managers.

Among other things, it checks their actual performance against planned deadline dates, and acts as a progress chaser by sending telex messages to remind managers of their obligations. At the end of the month, it evaluates the manager's place in the hierarchy of professional "emulation" and adjusts his pay accordingly.

The system, which operates with a staff of five, is said to repay the investment costs within a year by reducing inter-office correspondence by some 50%, as well as improve labour discipline. Its adoption has been recommended for all radio-engineering enterprises in the USSR. ☐

Another carcinogen?

from Laura Swaffield

THE problems of carcinogens in industry (see *Nature*, **258**, 94; 1975) are again highlighted by an article in the journal of the British Society for Social Responsibility in Science. The substance now implicated as a carcinogen is trichloroethylene, widely used as a degreaser and chemically similar to vinyl chloride monomer (VCM).

Its alleged link with humans will be harder to prove than with VCM, which is said to produce a rare form of cancer (angiosarcoma). And whatever the eventual findings, enforcement of controls may be difficult. Trichloroethylene is an important cause of gassing and is well known already as a narcotic with dramatic effects.

Precautions are laid down in the UK, though they are by no means always met, and it remains debatable whether enough attention has been paid in the UK to its longer term effects. □

Continuing crisis in Italian universities

from Gillian Boucher, Venice

AS the *Corriere della Sera* put it on November 5, "Today the universities are opening: Why?" The article, concerned with the colossal extent of graduate unemployment in Italy, touched on only one of the problems of the universities—problems that seem so daunting and so far from being soluble by the universities themselves that one marvels to see concerned professors still perfectly sane and conducting themselves in a manner not dissimilar from that of their colleagues in more fortunate countries.

But with the universities open to all who have passed the state school-leaving examination, laboratory and library facilities for teaching are hopelessly inadequate. It is not uncommon for professors to cope with their swollen classes by giving the same lecture three times in a morning. A much tougher entrance examination, even if it were politically acceptable, would not be a fair way of selecting students for science courses because of the bias of the school curriculum: Petrach and Dante loom larger than science for the average Italian schoolchild.

Many university teachers would welcome instead a tough examination at the end of the first year of university, but even that smacks too much of elitism to be politically acceptable at present. Fortunately many students drop out voluntarily. Last year at the University of Padua there were 2,500 first-year medical students, 1,000 in the third year and 500 in the sixth, final year.

Medical schools are in a particularly difficult position, for they have to compete for medically qualified staff with hospitals, which pay far better. The large pay increases recently awarded to hospital doctors mean that university departments often have to fill their junior posts with people lacking medical qualifications, further increasing the teaching load of medically qualified professors.

Difficulties in recruiting first-class graduates are not confined to medical departments. The chief problem is that since 1973 there have been created no more *assistenti*—junior lecturers waiting for a chair who have a certain amount of security and who consider themselves definitely part of the establishment. Now *assistenti* are being replaced with *contrattisti*, who have only a four-year contract and no certainty of a university career beyond that.

Restructuring at the top of the ladder is causing perhaps even more of a headache. The 3,000 top professors (known as *professori di ruolo*) have, with the growing student numbers, been aided by more and more assistant professors, or *professori incaricati*. Although this arrangement was obviously cheaper for the state, in 1973 it was finally decided that 7,500 new *professori di ruolo* should be created by competition: 2,500 in 1973–74, 2,500 in 1974–75, and a further 2,500 in 1975–76.

In the competition, a candidate's publications are assessed by a committee of *professori di ruolo* in the candidate's field, the committee's decision being subsequently blessed by the Ministry for Public Instruction and the university concerned. Unlike previous competitions of this sort, in which the committees used to be elected by all the *professori di ruolo* in a field, the names of the members of the committee are now picked out of a hat by the Minister for Public Instruction. This system has not prevented unconscionable delays in the formation of the committees—mostly caused by obstructive *professori di ruolo* who did not wish to see their privileges diluted by numbers.

The final and fundamental problem is that of money. Once the ministry has spent what it considers necessary for school and university teaching, the sum remaining for research is usually enough to pay for the animal houses and the telephone bill. University research is saved only by the Consiglio Nazionale delle Ricerche (CNR) which, as well as supporting autonomous institutes, funds institutes in university departments and provides grants for individuals.

Anyone lucky enough to be funded by the CNR can feel comparatively secure until 1980, the end of the coming quinquennium. But the CNR is moving towards a Rothschild-like attitude to research for the consumer and may become unwilling to fund projects which fall outside its own guidelines. If a new body being canvassed at present, a Ministry of Scientific Research, is ever created, the CNR would probably become its executive branch. Then, with research firmly separated from education, the CNR would no longer fund research in universities. And that would be the death of science in Italian universities. □

Eurospace body acts

from Angela Croome

IT hasn't taken long for the recently formed European *ad hoc* Committee for Space Science to go into action. Just a week after the European Science Foundation in Strasbourg agreed to its formation, two members of the committee attended a Washington meeting of the Space Sciences Board of the US National Academy of Sciences—the committee's American counterpart as a clearing house for long term research policy in the space sciences.

Active subjects on which high level international planning and cooperation are sought include the proposals for an International Planetary Decade being sponsored by the International Council of Scientific Unions' committee for space research, COSPAR, and the project for a large space telescope as an international research facility. A joint meeting of the American board and the European Committee on the telescope is expected before long.

There is likely to be a good deal of overlap between both the business and the membership of the European committee and a similar committee formed to concern itself with astronomy—though the latter has an initial lifetime of only a year, whereas the space sciences committee is to operate for two years.

The newly formed committee will want to keep an eye on the European Space Agency, established earlier this year, most of whose funds have gone on technology projects, principally satellite applications, rather than scientific research. The agency itself accepts that the balance is not right at present.

In the UK, meanwhile, the Director of Jodrell Bank, Sir Bernard Lovell, has said that the large area interferometer system financed through a £1.9 million grant from the Science Research Council is unmatched in its scale and sophistication. He also sees it

Lowering costs in higher education

KENNETH MELLANBY

When in 1947 I went to Nigeria to try to start that country's first university at Ibadan, I had a capital sum of £1.5 million provided by the British government for buildings. Tough negotiations persuaded the Nigerian government to increase its proposed annual grant (to meet other costs) from £60,000 to £100,000. These sums soon proved to be inadequate and larger amounts eventually became available; but until oil was discovered in the country we were always short of money.

I therefore find it hard to be as sympathetic as I should to the universities of the UK in their present financial position. After all, their grant from the goverment has increased by some 200 times in 25 years. I think that it is right that their expenditure should be carefully scrutinised.

There is growing concern about student numbers and the entry into different faculties. Politicians and others have suggested that money should not be spent on training specialists for jobs which do not exist, especially when the training is particularly expensive. Unfortunately, attempts to relate graduates to jobs have seldom been successful. Thus in medicine we had the Willink and Goodenough committees, which restricted the growth of medical schools at a time when expansion was later shown to have been needed.

Yet this should have been a comparatively easy exercise for, notwithstanding the egregious mistakes of our demographers (who in 1945 estimated that by 1965 Britain's population would fall by 4 millions, though in fact it increased by about the same number), the number of patients and their diseases remains fairly constant year by year. Few people would suggest at present reducing our intake of medical students, even though it costs the taxpayer something like £100,000 to train a qualified doctor.

Universities claim, with some justification, that they need to maintain a good academic balance, and that one faculty should not grow so rapidly that it overshadows the others. Some even believe that there is an ideal ratio for the number of students in different faculties. I remember hearing Lord Hailsham, when in charge of higher education some twelve years ago, deploring the insistence of universities on enlarging their faculties of law and social science, even when there was no increased demand for lawyers and social scientists, as a condition for producing the larger number of scientists for whom there seemed, at that time, to be a demand. Sadly, some of the increased number of scientists found, after graduation, that they were also unwanted. To estimate future manpower needs is clearly difficult.

When funds are plentiful, there is less demand to regulate entries into expensive courses. We are rightly proud of our high academic standards, and resist attempts to lower them. Nevertheless more thought could be given to reducing costs. If we are admitted to a British hospital, we will probably be attended by a doctor who qualified in India or Pakistan. Some may arrive with inadequate English and others (like, unfortunately, some of our own graduates) may be incompetent. But the majority carry out their duties admirably. Yet the cost of their training was only a fraction of that incurred in the UK. It is difficult not to believe that there is some room for economy, even in medicine.

Veterinary training is not quite so expensive, but costs probably amount to about £50.000 a graduate. This is justified because the veterinary surgeon makes an important contribution to food production by his care of farm animals. The present trend will double the number of vets in practice in Britain within the next 20 years. It is right to wonder whether this is wise or prudent. At present more than half of veterinary practice is devoted to what are, rather charmingly, called 'companion animals'. These are pets, dogs, cats and also horses and ponies. Now it would be wrong to suggest that these are unimportant. They bring pleasure to many, and companionship and solace to elderly and lonely people. They need to be cared for.

But it is surprising to find that some 6 million dogs, rather fewer cats and 250,000 horses take up more veterinary time than do 50 million farm animals (cattle, sheep and pigs) and nearly 150 million poultry. If our farm animals are receiving anything like proper attention, some companion animals would seem to be over-privileged, particularly as experience suggests that the only contact many dogs and cats have with a vet is to be put down when they are old or unwanted. If, as many expect, the number of intensively kept farm animals falls substantially as supplies of cheap imported feeding stuffs dry up, will we need as many vets for agriculture? Can we afford them for our pets?

It is generally agreed that all our school leavers able to profit from higher education should have the opportunity to do so, but need this be so expensive? Can we really justify a staff–student ratio three or more times as high as that obtaining in many other countries? Has enough attention been given to devising more general—and less expensive—courses? We often hear that change in science-based subjects is so rapid that every practitioner will have to be retrained at least once every 10 years. Are we devoting enough of our scarce resources to retraining, and might it not be better to reduce the scale of that given initially?

No doubt these problems are in many people's minds, but so far changes have generally raised rather than lowered academic costs. Perhaps the financial crisis will ensure that action is taken to reduce waste and still to maintain standards.

---

as an important step towards the 375-foot radio dish planned for the observatory's Meiford site in Wales, some 85 km away.

The new facility, which will use three existing radio dishes that are capable of working down to centimetre wavelengths, will also increase the interferometer baseline from 20 to 85 km by adding a new 25 m low cost dish in Montgomeryshire. The whole system will be centrally controlled from Jodrell's new interferometer control room

"The new facility will not replace the 'big dish'—it simply makes the best use of the equipment and expertise we already have", says Sir Bernard. As for the 'big dish', he still hopes to finance the 375-footer at Meifod. Plans had to be dropped two years or so ago because the international tenders were far higher than expected: £16 million as against an estimated £10 million □

correspondence

Computer prehistory

Sir,—Professor Wilkes (October 16) identifies the prehistory of computers with "the life's work of just one man, Charles Babbage (1792–1871)". If Babbage's work is likened to the prehistory of the subject, how is one to classify the elaboration of the real first arithmetical machine, almost two centuries earlier, by Blaise Pascal?

Pascal invented and built his arithmetical machine in 1643, at the age of 19, and obtained a patent for it (*Privilège pour la Machine d'Arithmétique de M. Pascal*) in 1654, at which time he had already constructed more than 50 different models. Although Babbage wrote in rather denigrating terms of "the contrivances of Pascal and others" (which actually worked) as compared to his own engines (which did not), Pascal's invention was indeed fundamental, and the actual precursor of all mechanical computers, including Babbage's.

A number of Pascal's machines are still in existence, for example, at the Conservatoire des Arts et Métiers in Paris. A detailed description of the mechanism and principles of Pascal's arithmetical machine was published in 1751

EEC directives

Sir,—As a member of the Conservation Society since its inception, and being much concerned about pollution, I would like to support Eric Ashby (October 16) against Paul French (November 6) The latter may be right in his final statement to the effect that other Europeans are more willing to tackle pollution than are the British. As a result of their efforts, for all I know, the Rhine may now, like the Thames, have more fish in its lower reaches than it has had for 150 years.

But his insistence that identical risks should apply everywhere is absolutely unreasonable. In the denser parts of big cities a complete ban on the burning of smoky fuels has reduced by several times the level of smoke pollution. It would not have been sensible to apply the same rules to villages and isolated farms in the country. Not only would uniform laws for town and country have led to a large extra cost for little useful achievement, but, much more seriously, such laws would never have been passed. I do not believe that in any country in Europe costly and novel proposals, however valuable in the long run, will fail to arouse some opposition. If they can be shown to be technically unreasonable over large areas, opposition will be much greater.

I can see that administrators like to have a uniformly applicable formula, against which performance can be judged. The new formula, which says that pollution is equally important everywhere, is a real advance on the previous non-formula which in effect said that most pollution was of no importance whatever.

It would not seem any more difficult, however, to use a formula which recognised that pollution is more important if more people are polluted. One would do better with a formula based on the square of this number, since if an area has twice as many people they are likely to produce twice as much pollution and there are twice as many to suffer this double pollution. A linear system (the importance of pollution being finite for zero population) would be much easier however, as the standard effluent permitted in any area could then be fixed only in terms of the slowly changing population in the affected area and not at all by the statistically larger fluctuations of the numbers of polluting factories.

Like Mr French, I would be entirely in favour of Britain spending £100 million a year on reducing pollution (and simultaneously, perhaps, unemployment). But to spend this on reducing pollution in the Atlantic Ocean rather than in the thousands of kilometres of rivers in which no fish can live would be a technical and economic stupidity that has nothing to do with politics or nationalism.

John H. Fremlin

University of Birmingham, UK

Sir,—I am not prepared to accept the whole of Lord Ashby's thesis, contained in his comments on the EEC pollution debate. He states, for instance, that "rabid conservationists need to be reminded sometimes that all pollution, except that from atomic weapons, is a by-product of processes which benefit society" I would have thought that conservationists—rabid or otherwise—are merely saying that any process which endangers the environment for future generations cannot possibly be regarded as beneficial to society.

Again it seems to me complacent, to say the least, to accept a report published by the Medical Research Council 16 years ago as a justification for pouring more sewage on to our beaches and noxious chemicals into our rivers, even though myriads of microbes may be working late into the night to lessen this evil.

Lord Ashby also refers to the phoney arguments. What can possibly be more phoney than his own argument that a cost of £100 million to reduce pollution is prohibitive when we spend many more millions every year on luxuries such as gambling?

Offshore structures

Sir,—We have had some experience with modelling offshore structures in the laboratory, and wish to call attention to the need for better understanding of the engineering problems likely to arise as drillings are made in deeper and deeper water. Mishaps that have already occurred have been serious enough, but the failure of one of the giant rigs or platforms now being planned would be a catastrophe of unprecedented proportions.

Waves not only exert the major load, which is horizontal and fluctuating, but they also affect the sea bed under and around the structure. The interaction is complicated and difficult to model, but studies and fragmentary prototype data have provided some clues. The foundation and anchorage problems assume greater importance as structures grow in depth.

Although some research seems to be in progress, there is little doubt that it has only just commenced. The present programmes are carried out for private industry whereas research on hydraulic phenomena was formerly for government agencies. Past results were thus public, but the present research is mainly *ad hoc* and confidential, in the long term being more costly to all concerned. Reasons for mishaps now tend to be kept secret for political or commercial reasons.

Basic issues should be investigated openly by university and similar institutions, if only so that controlling authorities and insurance agencies can establish design criteria.

Histocompatibility antigens and immunoglobulins?

from Alan F. Williams

In higher vertebrates there is a chromosomal region which contains closely-linked genes for histocompatibility antigens, and also genes which regulate immune responses. The major histocompatibility antigens which are recognised by antibody are called H-2 (K and D) and HLA (-A and -B) antigens in mice and men respectively, and seem to be coded for by two loci which are polymorphic within a species. The function of histocompatibility antigens is unknown, but the finding of genes controlling immune function in the same chromosomal region has led to the idea that histocompatibility antigens may also be involved in tissue interactions as cell-surface receptors. Taking this idea further, it has been suggested that these antigens may be related evolutionarily to immunoglobulin (see Bodmer, *Nature,* **237,** 139; 1972; Schreffler and David, *Adv. Immun.,* **20,** 125; 1975, for reviews).

Recent biochemical studies on histocompatibility antigens of mouse, man and rat have shown that they are carried by the polypeptide chain of a cell-surface glycoprotein of about 45,000 molecular weight, and that closely associated with this, but not covalently bound, is another polypeptide of about 12,000 molecular weight which is not polymorphic. This latter molecule is β_2-microglobulin which shows amino acid sequence homology with immunoglobulin (see *Transplantn Rev.,* **21,** 1974). These findings have been interpreted as supporting the idea of a receptor function for histocompatibility antigen, and also the possibility that the 45,000 glycoprotein is related to immunoglobulin. In fact such is the euphoria which has been engendered, that virtually every product of genes linked to the histocompatibility antigen region is now being considered to be related to immunoglobulin (for example Capra *et al., J. exp. Med.,* **142,** 664; 1975). This all involves a number of extrapolations and it is relevant that neither immunoglobulin nor β_2-microglobulin genes are linked to the histocompatibility antigen region (see the reviews cited above and Goodfellow *et al., Nature,* **254,** 267; 1975)

It is obvious that the relationship between histocompatibility antigen and immunoglobulin can only be determined by comparison of amino acid sequences, but in lieu of such data more circumstantial similarities have been sought. Several workers (Strominger *et al., Transplantn Rev.,* **21,** 126; 1974; Cresswell and Dawson, *J. Immun.,* **114,** 523; 1975; Peterson *et al., Proc. natn. Acad. Sci. U.S.A.,* **72,** 1612; 1975) have suggested that histocompatibility antigens are composed of a four-chain structure of two identical 45,000 glycoprotein molecules plus two molecules of β_2-microglobulin linked by disulphide bonds between the large molecules. This is based on the apparent size of histocompatibility antigen in detergents determined from their hydrodynamic properties, and also by the finding of bands in SDS polyacrylamide gel electrophoresis which appear to be dimers of the large subunit. Other evidence cited as establishing a link between histocompatibility antigen and immunoglobulin is that the antigens may contain intrachain disulphide bonds like those in immunoglobulin, and that histocompatibility antigen has affinity for a bacterial product—staphylococcal protein A, which binds to immunoglobulin. One might describe the evidence for all these points as tentative, and interpretations relating to the size of the antigens in detergent may be incorrect. Thus Snary *et al.* (page 240 of this issue of *Nature*) have produced evidence suggesting that the molecular weight of HLA antigen in deoxycholate is incompatible with a four-chain structure.

There are difficulties in estimating the size of membrane molecules in non-dissociating conditions. Integral membrane proteins are usually solubilised by detergents of which they bind large amounts (Helenius and Simons, *Biochim. biophys. Acta,* **415,** 29; 1975). Tanford *et al.* (*Biochemistry,* **13,** 2369; 1974) have described methods for accurate estimates of molecular weight in detergent and from chemical composition, measurements of detergent binding, and sedimentation equilibrium data, molecular weights can be calculated. For this, milligram amounts of pure material are needed while at present, estimates of the size of histocompatibility antigens can only be made with detergent extracts of impure material. Under these conditions only the size of the detergent–antigen complex can be estimated. This is derived from measurements of Stoke's radius by gel filtration, and sedimentation coefficient and partial specific volume ($\bar{v}$) by zone sedimentation on sucrose gradients in H_2O and ^2H_2O (Meunier *et al., FEBS Lett.,* **24,** 63; 1972; Clarke, *J. biol. Chem.,* **250,** 5459; 1975). Analysis by gel filtration and sedimentation on sucrose gradients in H_2O is a minimal requirement and large errors will result, particularly if gel filtration only is used since most membrane proteins including cell-surface antigens behave as if asymmetric in detergents (Letarte-Muirhead *et al., Biochem. J.,* **143,** 51; 1974: Snary *et al., op. cit.;* Clarke, *op. cit.*). A $\bar{v}$ value is often assumed rather than measured, and this is reasonably valid if the detergent used is deoxycholate since this has a v of 0.76 ml g^{-1}, close to that of proteins and glycoproteins (0.7–0.75 ml g^{-1}). With non-ionic detergents whose $\bar{v}$ is about 0.9 ml g^{-1} a valid assumption of $\bar{v}$ cannot be made without detergent binding data.

Snary *et al.* solubilised HLA in deoxycholate and carried out gel filtration and zone sedimentation on sucrose gradients; a $\bar{v}$ value was assumed. From this, molecular weights which include bound deoxycholate of 88,000 and 78,000 respectively were obtained for A and B series HLA antigens. Similar data has been obtained for rat histocompatibility antigen in deoxycholate and the molecular weight was estimated to be 100,000 (Letarte-Muirhead *et al., op. cit.*). These values are more compatible with a two-chain structure plus bound detergent (minimum size 57,000), than a four-chain structure (minimum 114,000). Peterson *et al.* (*op. cit.*) estimated the molecular weight of HLA and H-2 in the non-ionic detergent NP-40 to be 130,000. This would be compatible with a four-chain structure with little detergent bound, or more likely a two-chain structure plus a large amount of bound NP-40.

If the antigen-detergent complex does not contain a four-chain structure then there is the difficulty of explaining the reason for the appearance of the 45,000 chain in SDS polyacrylamide gel electrophoresis. Snary *et al.* have suggested that this may be due to disulphide exchange either in stored membrane, or possibly during immunoprecipitation procedures. Clearly the experiments must be repeated in the presence of oxidising agents.

If one accepts that histocompatibility antigens may have a two-chain rather than a four-chain structure does this argue against a relationship between the antigens and immunoglobulin? Obviously not, and this merely points up the circumstantial nature of the current evidence. The matter can only be settled by amino acid sequence analysis of the 45,000 molecular weight glycoprotein which carries the antigens, and comparison of this with immunoglobulin sequences. Given the current progress in the purification of HLA and H-2, and also in microsequencing techniques, such data should be forthcoming in the next few years. ☐

Chemical language in insects

from our Insect Physiology Correspondent

It has long been known that scents produced by glandular organs play an important part in animal communication. The naming of such chemicals, used for communication between members of the same species, as 'pheromones' by Karlson and Lüscher coincided with the development of gas liquid chromatography, mass spectrometry and other methods which have made possible the chemical analysis of minimal quantities of material. The result has been a very rapid expansion of knowledge in this sphere. Whereas it took Butenandt and his associates many years and vast amounts of material to identify the chemical structure of 'bombycol', the female sex attractant of the silkworm moth, by classical procedures, complex mixtures can now be analysed in a matter of days

The chemicals present in the glandular secretions of insects are often exceedingly diverse; 20-30 recognised components in a single gland. They comprise a vast range of saturated and unsaturated hydrocarbons and their derived alcohols and aldehydes (ranging from hexenal and tridecene to pentadecane), fatty acids (such as butyric and caproic acids), a great number of phenolic substances and quinones (such as phenol, *m*-cresol, benzoquinone and toluquinone) and a variety of terpenoids (such as geraniol, farnesol, citral, and citronellol).

So far as the perceptions of man are concerned, in recognising the odours characteristic of particular kinds of shops, or appreciating the bouquet of a vintage wine, it seems to be the complex mixture which is assessed. Insects seem often to be concerned with a single component: in the mandibular gland secretion of the queen honey bee (as shown by Butler and his associates) there are more than 30 compounds; of these, 9-ketodecenoic acid is the 'queen substance' which attracts males during the nuptial flight and inhibits royal-cell building by workers in the nest, whereas 9-hydroxydecenoic acid causes clustering and stabilisation of worker swarms.

The action of pheromones is commonly divided into two classes (following Wilson and Bossert): chemical 'releasers' of specific acts of behaviour, and 'primers' which seem to act initially on the endocrine system The same pheromone may show both types of activity—as in the case of the queen substance which, besides its effects on behaviour, inhibits ovarian development in the workers. Moreover the same chemical can be used both as a pheromone for communication within the species and as an 'allomone' (as defined by Brown and Eisner) to provide defence against an enemy. That combination is well seen in the use of formic acid by the wood ant. Thus the effects of a pheromone depend on circumstances, on differences in concentration, and in some instances on the combination of secretions from different glands. It has even been suggested by Bossert that concentrations might be modulated in time. It is unlikely that the modulation of odour emission could attain the level of a symbolical or syntactical language but as E. O Wilson points out the acoustical system has acquired quite complex signal modulation in the songs of insects.

The signal provided by a pheromone is the 'active space' as defined by Bossert and Wilson· the zone around the point of emission within which the concentration of pheromone molecules is above the threshold level of response. This zone may vary in shape with movement of the air, and in composition depending on the comparative rates of diffusion of the varied molecules. As Wilson has pointed out "the relation of chemosensory physiology to ecology can be fully elucidated only through the analysis of the active spaces".

These ideas have been carried some steps further by interesting observations of Bradshaw, Baker and Howse on the multicomponent pheromones of the weaver ant *Oecophylla*, as described on page 230 of this issue of *Nature*. These authors find evidence of caste differences in the mandibular gland secretions as well as differences in the components to which the castes respond. Furthermore, they have made interesting advances in studying the changes in the 'active spaces' of particular components which appear to provide sequential messages determined by the volatility of materials and the threshold concentrations for different responses. Worked out in detail in relation to the mode of life of a polymorphic species, all this shows the immense potentialities of chemical communication in the regulation of behaviour in a social insect. ☐

Fibroblast model for hormone effects

from Robert Shields

One of the most striking features of the action of trophic hormones on cells is that many of the resulting changes in metabolism are remarkably similar, regardless of the type of hormone or the target tissue. Thus changes produced by oestrogen in the uterus, corticosteroids in the liver and insulin in muscle are much the same. These changes include alterations in macromolecular synthesis and a great deal of endocrinological research has been directed at finding out how hormones regulate these processes. The classical endocrinological approach has been to remove the gland producing the hormone under study and after a suitable period re-add the hormone and follow the subsequent changes in the target tissue. Although much qualitative data has been gathered in this way, the lack of suitable *in vitro* systems has hampered a quantitative assessment of the inter-relationship between the hormone-induced changes in RNA, protein and DNA synthesis.

One well known *in vitro* system that has been studied intensively (but for rather different reasons) is the control of growth of fibroblasts in tissue culture. It now seems apparent that the growth of these cells is regulated by the levels of serum factors available to the cell (*News and Views,*

253, 689; 1975) and that these factors are probably hormones which have not yet been fully characterised. Decreasing the availability of serum to cultured cells either by reducing the serum concentrations or allowing the cells to reach confluence is the *in vitro* equivalent of removing the gland producing the trophic hormone, re-adding the serum is the equivalent of hormone replacement Since the changes in metabolism induced in serum-stimulated fibroblasts are very similar to those produced by trophic hormones (Hershko *et al.*, *Nature new Biol.*, **232**, 206; 1971), a study of the changes induced in these cells may give clues as to how trophic hormones operate *in vivo*.

Rates of macromolecular synthesis are almost invariably assayed by incorporation of radioactive precursors, and the accuracy with which the incorporation rate reflects rates of synthesis is open to question. An alternative indirect approach depends on assaying steady state concentrations and rates of degradation of macromolecules. The inferred rates of synthesis can then be compared with those from tracer studies. By this method it has been deduced that growing fibroblasts have about four times the protein synthetic rate per unit protein than non-growing cells and differences of this order of magnitude have indeed been suggested by labelling studies (Rudland, *Proc natn. Acad. Sci. U.S A.*, **71**, 750; 1974). In principle this approximately four-fold increase in protein synthetic rate could be produced by controlling the levels of cytoplasmic mRNAs and/or controlling the rates at which the mRNAs are translated. The question as to which of these events is dominant in the hormonal stimulation of protein synthesis has long been keenly debated, the cultured fibroblast provides an ideal system for measuring their relative importance.

It is conceivable that the translation of mRNA into protein could be governed by the availability of ribosomes. In growing cells rRNA appears to be stable (Weber, *Nature new Biol.*, **235**, 58; 1972; Abelson *et al*, *Cell*, **1**, 161; 1974), but in non-growing cells the rRNA turns over at about 1% per h This gives a relative rate of rRNA synthesis in growing compared with non-growing cells of about four-fold based on their relative RNA content, or about eight-fold on a per cell basis. Cells which have just been stimulated would have intermediate rates of rRNA synthesis, and this has been confirmed by labelling experiments (Bandman and Gurney, *Expl Cell Res.*, **90**, 159; 1975; Rudland, *op. cit.*). How these relatively large differences in the rates of rRNA synthesis are achieved is not yet clear. Certainly increased transcription of rRNA genes occurs (Emerson, *Nature new Biol*, **232**, 101, 1971; Mauck and Green, *Proc. natn. Acad Sci. U.S.A.*, **70**, 2819; 1973) but whether there is also less wastage of rRNA precursors as seen in stimulated lymphocytes (Cooper, *Nature*, **227**, 1105, 1970) is not known. But although the increased rate of ribosome synthesis in cells recently stimulated can hardly have any impact on the total ribosome content for some hours, the increased rate of protein synthesis is observed very rapidly. This must mean that some other feature of the protein synthetic machinery is altered

Keen proponents of the applicability of the Jacob-Monod model to mammalian systems might suggest that an increase in mRNA content is responsible. In both growing and resting cells the half-life of mRNA is the same (Abelson, *op. cit*) and corresponds to a degradation rate of 8% per h This would mean that the relative rate of mRNA synthesis in growing and resting cells was 1.4 times their relative mRNA contents Here there is some conflict in the literature Using steady state labelling Johnson and his coworkers (*Cell*, **1**, 95, 1974) claim that resting cells contain two to four times as much mRNA on a per cell basis as resting cells On the other hand, using a method of quantitating mRNA by hybridising ^{3}H-poly(U) to the poly(A) tracts of mRNA, Rudland and his collaborators found at the most a 30% increase in growing cells (*J. molec. Biol*, **96**, 745; 1975). The former estimate would give a relative rate of mRNA synthesis of three to six-fold on a per cell basis, the latter a 1.6 to 1.8-fold increase in growing cells. In fact, analysis of the rates of appearance in the cytoplasm of ^{3}H-poly(A) tracts attached to mRNA gives a relative rate of 1.8-fold in stimulated cells (Bandman and Gurney, *op cit.*), suggesting that the relative mRNA contents of growing cells may be only marginally higher than in resting cells. One unexpected result from these experiments is that the increase in mRNA synthesis seen in growing cells is not due to an increase in gene transcription but rather to an approximately two-fold increase in the efficiency with which mRNA molecules are clipped from their high molecular weight precursors in the nucleus (Johnson *et al*, *Cell*, **4**, 69; 1975). In any event, the small increase in mRNA content in growing cells is not sufficient to account for the approximately four-fold increase in the rates of protein synthesis seen in stimulated cells, especially since the increase is so rapid.

When the cytoplasmic location of poly(A)-containing mRNA in non-growing cells was examined, it was found that a significant amount of mRNA, variously estimated at between 37% (Bandman and Gurney, *op. cit.*) and 85% (Rudland *et al.*, *op cit.*) was not associated with polysomes, but was in the form of slowly sedimenting ribonucleoprotein particles On stimulation this mRNA was rapidly recruited into polysomes which are formed at the expense of free ribosomes. A number of indirect experiments show that the existence of mRNA in these particles is due to a low rate of initiation of ribosomes on mRNA After stimulation this rate is rapidly increased (Rudland *et al.*, *op. cit.*; Bandman and Gurney, *op. cit.*). It seems that the increased rate of initiation of ribosomes on mRNA and the resulting recruitment of pre-existing untranslated mRNA is sufficient to account for the rapid increase in protein synthesis seen after serum stimulation. Later, the extra concentration of mRNA and ribosomes will help maintain the high rates of synthesis.

The conclusion reached from these results is that the substantial changes in the general rate of protein synthesis seen in stimulated cells are governed largely at the translational level rather than at the level of mRNA transcription Gratifyingly, similar conclusions have been reached using much more indirect experiments for the action of trophic hormones *in vivo* (Korner, *Ciba Foundation Symposium*, **86**, 1970). Induction of specific proteins in animal cells however such as the induction of oralbumin by oestrogen in the Chick oviduct, may rely more on changes in the amount of specific mRNAs. ☐

Man against nature in the climatic stakes

from John Gribbin

LATEST indications suggest that all of man's polluting influences on climate may be acting to produce a global warming, while the natural trend extrapolated from past variations is towards a cooler regime. In the short term, the former influence may well dominate, and this suggests the need for a radical rethinking of some predictions, such as those concerned with the impact of climatic change on agriculture and world food production.

Until recently, it could be argued that some aspects of man's activity cause a warming tendency (CO_2 and the greenhouse effect) while others tend to cool the Earth (atmospheric dust) so that on balance they might be ignored. But last year several calculations were published showing that the net effect of the aerosol dust particles might also be to cause a global warming (*Nature*, **253**, 162; 1975). More recently, R. A. Reck has suggested that the present background aerosol density should be contributing a temperature increase of 0.2 K at 85°S and 0.05 K at 85°N, acting to oppose the increase in snow and ice cover in 1971 which some climatologists have linked with circulation changes associated with the Sahelian droughts of the early 1970s (*Science*, **188**, 728; 1975). The difference in the size of this effect in the two hemispheres arises because it depends on the relative albedos of the aerosols and the underlying surface, and there is of course much more land in the north.

So what of the greenhouse effect? Considering CO_2 alone, and ignoring any effects due to dust, W. S. Broecker has suggested that a pronounced warming could become apparent within a decade (*Science*, **188**, 460; 1975) There have been many calculations of the direct warming which would be caused by a specific increase in CO_2 content of the atmosphere, and although these have not always agreed with one another the differences between them are now small enough for Broecker to produce a plausible extrapolation of the exponential growth of this contribution to global temperature up to the end of this century. Where his study goes a step further than those of most workers is in combining this warming trend with an extrapolation of the 'natural' trend of temperature from the pseudo-periodic fluctuations of the ^{18}O record in the Camp Century ice core.

The combined effect of the two processes is likely, on this model, to produce dramatic changes in the near future. The natural cooling phase since the mid-twentieth century has been opposed by the growing greenhouse effect, the net result being only a modest cooling; but according to the ice core evidence, this trend is likely to reverse within ten years, and from then until the end of this century the natural trend and the greenhouse effect will combine to produce a pronounced warming, increasing mean global temperatures by half a degree or more above the present level. According to Broecker, the greenhouse effect would then be operating so strongly that future natural cycles with the 80-year Camp Century 'period' would serve only to modulate the ever steepening rise in temperature. This, he says, "by early in the next century will have driven the mean planetary temperatures beyond the limits experienced during the last 1,000 years". In fact, that may be no bad thing, since the past millenium has been, by and large, cold and unsuitable for the world to support anything like the population expected for the end of this century. But as Broecker stresses, the agricultural consequences of such a warming are not obvious, and we do not know how a change in mean global temperature would be likely to affect rainfall patterns in the all important grain producing regions.

Some aspects of Broecker's study are certainly speculative, but none the less stimulating in highlighting the need to consider the possible impact of such a warming, and not to be too restricted and look only at the problems posed by cooling trends. The need to avoid the stereotyped approach is also highlighted by the discovery that chlorofluorocarbons—familiar to doomwatchers as possible destroyers of the ozone layer—may also contribute directly to climatic change, again through a greenhouse effect.

These compounds are strongly absorbing at infrared frequencies, and V. Ramanathan calculates (*Science*, **190**, 50; 1975) that if the concentration of them in the atmosphere reaches two parts per thousand million there could be a corresponding increase in surface mean temperature of more than 0.25 K. This is the concentration which may be reached by the year 2000 if present levels of injection continue (Molina and Rowaland, *Nature*, **249**, 810; 1974), and although smaller than the projected CO_2 influence this would be significant alone. With this effect and perhaps the aerosols adding to the CO_2 effect there seems nothing to oppose the warming influence of man's polluting activities except the natural variations of climate.

Those natural variations must dominate in the long term, and even within a hundred years of CO_2 production at the rate implied by Broecker's extrapolation there will be little prospect of further significant increases since there will be little fossil fuel left to burn. So the pronounced global warming he envisages is, even if genuine, only likely to be a short term phenomenon, assuming that plants continue to take up CO_2 from the air. Looking further ahead to the next 1,000 years (which is a short enough span in climatic terms), the overall cooling tendency of the globe is likely to continue into a full ice age, according to studies of isotope variations in cores drilled from the floor of the Antarctic sea. These studies, made by a team at Lamont-Doherty Geological Observatory, were reported to the recent Norwich conference on climate by J. Hays.

Hays' interpretation of long term climatic fluctuations from this evidence provides strong support for the Milankovitch theory that changes in the tilt and precession of the Earth affect insolation at critical latitudes sufficiently to cause ice ages, and suggests that while ice ages are roughly synchronous in the two hemispheres the south leads the north by a few hundred or a thousand years. Since the most recent sediments show isotope variations implying that the southern hemisphere has already begun to move towards a new ice age, the conclusion that a full global ice age is due within a millenium follows inevitably from this interpretation of the past variations. In that case, and looking at the lifetime of our civilisation rather than that of an individual, it seems we should make the most of any warm spell we do get in the coming decades, since there is a long cold spell to follow. □

Ecological carousel

from Peter D. Moore

ECOLOGISTS, like the Greeks, are seekers after ideals. Among conceptual ideals, none is less tangible, or more sought after, than that of the ecological climax. The idea of the perfectly stable, equilibrium ecosystem which has developed through a sequential series of successional stages, is a very attractive one, but even as the concept evolved in the minds of such men as Clements, it gave rise to ecological controversy. The Clementsian ideal of a climax system in equilibrium with climate was soon demonstrated to be impracticable when applied by Tansley to vegetational studies within the British Isles. Tansley insisted that stability was the essence of climax and therefore any overriding factor of the environment, be it edaphic, topographic or biotic, which limits the development of an ecosystem short of its potential climatic climax state, can be the determinant of a climax system.

The development of ecosystem theory in recent years has necessitated a restatement of the climax ideal, and this has been provided by Odum (*Science*, **164**, 262; 1969), who based his definition on the characteristic energy flow and nutrient cycling patterns to be expected from a steady-state system. In practice, however, as in the case of the Clements–Tansley debate, much depends upon the scale, both temporal and spatial, on which any system is being studied. Apart from natural calamities, which are of frequent occurrence in many ecosystems (see Loucks, *Am Zool*, **10**, 17; 1970), the inevitable death and collapse of climax dominants, particularly in forest ecosystems, will result in renewed succession with a frequency dependent upon the generation time of the dominant. Consequently, the stable system found in the real world consists of a mosaic of microsites each of which may be in a different state of successional development or dominant maturation. The whole system may, nevertheless, approximate to the Odum ideal in terms of its energy and nutrient balance sheet.

This state of affairs is well documented in a recent study by Forcier (*Science*, **189**, 808; 1975) of the canopy tree species in a forest in New Hampshire. Within this forest, 90% of the trees belonged to one of three species, namely beech (*Fagus grandifolia*), sugar maple (*Acer saccharum*) and yellow birch (*Betula alleghaniensis*). Forcier observed 400 randomly chosen plots within this forest over a period of three years and paid particular attention to the population dynamics of the seedlings of these species. Mortality of beech seedlings was found to be high initially but declined with age, thus average life-expectancy increased. Birch, on the other hand, had a fairly constant mortality whatever the seedling age. Sugar maple was intermediate in its population dynamics. Also, beech seedlings were found to vary little in their density whilst birch seedling densities varied considerably and average density was more than five times that of beech. These data suggest that birch is behaving as an opportunist in the composition of the forest.

Association analyses between the seedlings and the canopy trees showed that sugar-maple seedlings were associated with birch canopies and beech seedlings with sugar maple canopies. Evidently the three species are related in a cyclic successional series in which disturbance (or death of a mature tree) leads to birch invasion, sugar maple fares well beneath the birch canopy, eventually replacing it, and finally beech invades and replaces sugar maple. The roughly equal abundance of the three species of tree in the canopy is indicative of the importance of this cyclic microsuccession in what appears superficially to be a stable, 'climax' forest.

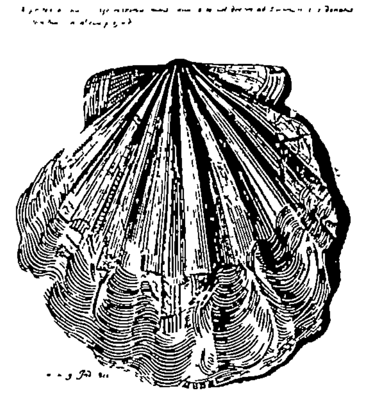
Forcier calls this a 'near climax ecosystem', but this is rather misleading, since it suggests that the system falls short of the ideal. In a sense it does, for the community consists of a mosaic of sites, most of which are in different stages of the cyclic development. Nevertheless, the forest as a whole complies with many of the demands of the Odum ideal. There is no net increase in biomass, so gross ecosystem production is equalled by ecosystem respiration Also the total input of nutrients from all sources (meteorological, geological and biological) must be equalled by total outputs. Reality fails to live up to the ideal only in that the 'stable' system contains species which cannot regenerate efficiently beneath their own canopy and which one therefore tends to associate with successional stages instead of the climax. Rather than call this forest a 'near climax', let us be ready to modify further the climax dogma and admit that climax is a carousel. ☐

What drives the solar cycle?

from Nigel Weiss

IAU Symposium No. 71 on Basic Mechanisms of Solar Activity was held in Prague on August 25–29, 1975.

THE Sun is the only star that can be observed in detail and any theory of stellar structure must be tested against these observations. Unfortunately, conventional models cannot explain the low measured neutrino flux or the excitation of oscillations in the Sun. as I. W Roxburgh (Queen Mary College, London) put it, "solar physics has forced the stellar physicist to think again." Over the past few years solar physics has developed, rapidly Observationally, it has become possible to resolve structures with scales smaller than the photosphere granulation, while theory is advancing from simple mechanisms to detailed computations.



Reproduction of the illustration of the earliest figured and described fossil from America. From Lister's (1687) *Historiae Conchyliorum Liber III.* Lister's entire description is with each figure and not in a separate text. Say (1824) mentions this figure as being his species *Pecten jeffersonius.* (Reproduced from *"Chesapecten,* a new genus of Pectinidae (Mollusca: Bivalvia) from the Miocene and Pliocene of Eastern North America"—*Geol. Surv. Prof. Pap. 861*

The solar cycle is apparently typical of stars with convective envelopes and O. C. Wilson (Hale Observatories) has found similar behaviour in several late-type stars. Magnetic fields on the Sun have been observed in profuse detail, from satellites and from the ground; indeed, we have far less information about fields in the Earth's core, which is shielded by the mantle. It is generally accepted that the cycle is maintained by an oscillatory dynamo yet E N. Parker (University of Chicago) emphasised that many features of this process are still poorly understood.

The orthodox model is a dynamo driven by a combination of differential rotation and helical motion in the outer convective zone. A dipole-like field is wound round the Sun by differential rotation and the resulting toroidal field is twisted by helical convection to produce a reversed poloidal field. Samples, particularly of the strong toroidal field, pop through the surface in active regions. This process can be represented by mean field electrodynamics: F. Krause and K.-H. Rädler (Zentralinstitut für Astrophysik, Potsdam) described the procedure of separating large scale mean fields from small scale fluctuating fields and then averaging over space or time Turbulent convection provides an enhanced eddy diffusivity and, through helicity (the α -effect), generates the poloidal field. Turbulence also produces fluctuating fields which, in the Sun, may be 100 times greater than the mean field itself. M. Stix (Göttingen University) discussed numerical solutions of the linear dynamo equations. With carefully chosen distributions of helicity and angular velocity, these yield remarkably accurate reproductions of the actual solar cycle.

Mean field electrodynamics is not perfect, however. The growth of the field is limited by non-linear effects that are not properly incorporated in the theory Moreover, the procedure of averaging and smoothing cannot be justified for giant convective cells and highly concentrated fields. J. O. Stenflo (Lund University) has established that more than 90% of the photospheric magnetic flux is concentrated into small regions, a few hundred kilometres across, with fields of around 1.500 gauss. Outside these regions, except in pores and sunspots, only weak, irregular fields are detected. To describe such a jagged field distribution, a more elaborate theory is needed.

Unfortunately, the pattern of motion in the deep convective zone remains unclear. R. Howard and H. Yoshimura (Hale Observatories) have accumulated Doppler measurements of the differential rotation which also provide some evidence for the existence of giant cells extending through the whole depth of the convective zone W. J. Wagner (Sacramento Peak Observatory) showed that coronal holes have an almost constant rotation rate which, with the sector structure of interplanetary fields, suggests the presence of cells elongated parallel to the rotation axis of the Sun. There is as yet no adequate theory of vigorous convection in a compressible fluid, though the interaction between convection and rotation has been studied for incompressible fluids. B. R. Durney (National Center for Atmospheric Research, Boulder, Colorado) found that the observed uniformity of the energy flux at the solar surface seemed incompatible with an angular velocity that increases inwards (as required for dynamo models). P. A. Gilman (NCAR) described numerical experiments on convection in a rotating spherical shell which led to large variations of angular velocity, though not necessarily to an equatorial acceleration. It is through such large scale computations that further theoretical progress must be made.

Turbulent diffusion is an essential feature of any solar dynamo, though there is no complete theory for the reconnection of magnetic fields on a sufficiently rapid time scale. The generally accepted view is that turbulence can bring opposing fields close enough together for dynamically driven reconnection to take place. E. R. Priest (St. Andrew's University) and A. M. Soward (Newcastle University) demonstrated that rapid reconnection can occur at rates up to the Alfvèn speed. J. H. Piddington (CSIRO, Sydney) dissented from the orthodox approach. He believes that turbulence may redistribute magnetic flux but is unable to destroy it. Indeed, his magnetic fields form isolated flux ropes that control the pattern of cellular convection (instead of being concentrated by the motion). So he has revived an alternative model of the solar cycle, relying on a primordial steady poloidal field from which the alternating toroidal field is generated by some form of torsional oscillation.

Immunological tolerance

from a Correspondent

> A symposium on Immunological Tolerance was held at Reinhardsbrunn, GDR on October 14–17. It was sponsored by the International Union of Immunological Societies and the World Health Organization.

THE mechanisms of antigen-induced unresponsiveness (immunological tolerance) are still controversial: tolerance has been ascribed either to "deletion" of relevant lymphocyte clones, or to active suppression of these clones by other lymphocytes (T suppressor cells) or by humoral "blocking factors".

The classical concept of clonal deletion in tolerance to transplantation antigens, first propounded by Sir MacFarlane Burnet and others, has withstood the test of time. Experiments by H. von Boehmer and J. Sprent (Basel Institute for Immunology) with mouse radiation chimaeras (F_1 hybrid mice reconstituted with bone marrow cells from both parents), provide clear evidence that self-tolerance in these animals is due to clonal elimination and not to suppression.

Evidence for blocking factors in the maintenance of tolerance was also presented, however. H. Wekerle (Max Planck Institut, Freiburg) has induced autoreactive lymphocytes by coculturing lymph node cells and testicular cells from the same rat. The cytostatic activity of these cells is blocked by an unknown factor present in autologous serum, and to a lesser degree by serum from allogeneic rats. M. Embleton (Cancer Research Campaign Laboratories, Nottingham) discussed experiments showing that rats developing hepatomas first have free tumour antigen in their serum, and then antigen–antibody complexes. The latter are effective in "blocking" the activity of effector lymphocytes, and disappear from the circulation within 3 days of the excision of the tumour.

Inhibition of lymphocyte effector function by T suppressor lymphocytes was a major topic of discussion. Both K. Eichmann (University of Cologne) and Leonore Herzenberg (Stanford University) presented evidence that suppressor T cells act by inhibiting the function of helper T cells (cells which help B lymphocytes to make antibody). Data from A. Basten (University of Sydney) suggest, however, that under some conditions the target of suppression may be the antibody-forming cell precursor (B cell).

There were, nevertheless, close parallels between these three systems. Thus, suppressor cells seem to belong to a discrete T cell subpopulation—bearing Ia antigens, distinctive Ly antigens, and with a characteristic tissue distribution. Most strikingly, both Eichmann's and Herzenberg's work suggests that there are categories of helper T cells which only interact with a restricted B cell subset—those destined to produce a single allelic variant of one immunoglobulin subclass (Herzenberg) or a single idiotype (Eichmann). These specialised helper cells seemed to be the targets of suppression.

The general role of suppressor cells in tolerance remains unresolved. Basten presented clear evidence that although mice made tolerant with human gamma globulin developed suppressor cells, the animals remained tolerant long after the suppressors had disappeared. For the present one may conclude that, although suppressor cells are demonstrable in a number of tolerance models, they have not been shown to be obligatory either in the induction or maintenance of unresponsiveness. Rather, they may fulfil a more subtle homoeostatic function.

One session was devoted to tolerance induced by "suiciding" specific immune responses by attaching a lethal agent to an antigen, so that the complex inactivates clones of cells bearing receptors for that antigen. This conceptually attractive approach, with obvious potential therapeutic applications, has hitherto been largely restricted to animal models using highly radiolabelled antigens. Recently, however, H. Ambrosius and his collaborators at the University of Leipzig have been testing various immunosuppressive agents, in particular 6-mercaptopurine, coupled to protein antigens. Such conjugates specifically suppress anti-protein antibody synthesis in guinea pigs. D. A. L. Davies (Searle Research Laboratories, High Wycombe) is studying the effects of a phenylalanine mustard coupled to antitumour antibody on the growth of a transplantable mouse lymphoma. The results are encouraging: administration of the drug or antibody alone is ineffective, giving the drug at the same time as antibody is effective, while the covalent drug–antibody conjugate is even more effective.

The success of this meeting was undoubtedly partly due to the fact that it brought together experts in various aspects of tolerance, and enabled them to find common ground for a variety of phenomena. Most importantly, however, it also provided a unique opportunity for immunologists from the East and the West to meet and exchange ideas. ☐

A hundred years ago

AT its last sitting the French Geographical Society broached a scheme for inducing the several French Railway Companies to place at each station a map of the vicinity, with indications of the most notable historical or economical facts connected with the district. It appears that this is the universal practice on Brazilian railway lines.

Visual experience and cortical development

H. B. Barlow*

The past twelve years have been exciting for those interested in the classical question, "How much do our visual capacities depend on innate developmental factors, how much on the moulding effects of visual experience?" Recent papers[1–4] have settled some issues, but may start new waves of controversy, and this is the occasion for writing this review.

THE oldest source of knowledge on visual development is clinical, for ophthalmologists know from their experience with amblyopia that one eye can become almost completely functionless from lack of use. This most commonly occurs when the two eyes interfere with each other, either because of strabismus (squint), or because one eye has a much greater refractive error than the other, and it can be partially prevented and reversed, at least in its early stages, by patching the good eye, thus forcing the use of the "lazy" eye that is threatening to become amblyopic. In 1963, Wiesel and Hubel[5] reported similar effects produced in cats by interfering with the normal binocular use of their eyes in the first month or two after they opened, and they discovered that the underlying change occurs in the cells of the primary visual cortex (area 17). In normal animals a high proportion of these neurones receive connections from both eyes[6], but if one eye is covered soon after birth, it makes connections with very few cortical neurones, almost all of which are then found to be connected solely to the eye which has been in continual use[5]. Furthermore, if a kitten is made strabismic by sectioning an eye muscle, or if joint usage of the eyes is prevented by covering each of them alternately, their neurones are found to receive input from one eye or the other, but very few receive input from both[7].

In their experiments Hubel and Wiesel found that covering both eyes had comparatively little effect on the cells of the cortex, suggesting a competitive element in the causation of the changes from monocular deprivation[8]. This was confirmed by Sherman, Guillery, Kaas and Sanderson[9] who made retinal lesions in one eye and closed the other. They found reduced effects of deprivation in the parts of the visual field that had no competing representation in the open eye. Hubel and Wiesel[10] found cells in the cortex of very young kittens, before the age of eye opening, that were connected to both eyes and appeared normal in other properties, and they reproduced many of these results in monkeys[11]. The apparent normality of cells in very young visually inexperienced animals, and also in binocularly deprived ones, led them to believe that the functional pattern of connections that underlies normal vision are laid down by genetically determined developmental processes. These can be interfered with or disrupted by abnormal visual experience in the "sensitive period" of the first few months of life[12], but they did not think that normal visual experience had any constructive effect in setting up the neural apparatus in the primary visual cortex.

These very important experiments with their suggested answer to the ancient dispute about the role of experience have naturally aroused great interest, and some controversy has arisen about both the facts and their interpretation. By now most of the facts discovered by Hubel and Wiesel have been confirmed by others, but there have been further advances that will be considered under four headings: ocular dominance and binocularity; specificity without experience; disparity selectivity; and the degree of modifiability of cortical neurones.

Ocular dominance and binocularity

The effects on the monocular and binocular connections of cortical neurones have proved reliably repeatable, but interesting additional knowledge has been gained by the technique of reversed suture[13–15], in which the originally closed eye is opened and the originally open eye is closed. It seems that an eye that has become disconnected can be persuaded to reconnect by renewed visual experience, provided that this occurs during the "sensitive period" and provided that the newly opened eye does not have to compete with an already connected eye that is in continued use. Thus experience can certainly have a reconstructive effect, and it is particularly interesting that the reconstructed connections are different in several ways from the previous connections that had been disrupted by the period of closure. The most striking evidence for this is provided by neurones that are in the process of being taken over by the newly opened eye but can still be driven by the other, previously open, eye. Some of these are quite unlike any cells found in normal cortex in having widely divergent preferred orientations for the two eyes, the difference sometimes being more than 70°, which is never found in neurones of normal cats and kittens More information about this is obtained by examining the properties of the series of neurones encountered while advancing an electrode through the cortex, for the newly formed connections seem to develop a sequential pattern of orientational selectivity that is similar to the old pattern, but independent and often out of step with it[16].

The effects of deprivation are certainly easier to show than are those of experience, and a nice example of this was given by Olson and Freeman[17]. They found that 2–5 d of monocular vision had a profound effect on the ocular dominance histogram, but unexpectedly, it made no difference whether the animals had been reared in total darkness or in ordinary light before the monocular experience. For the deprived eye, several weeks of ordinary vision were undone in a few days of deprivation. Following reversed suture, however, one can see that experience encourages reconstruction, and one must suspect that normal joint usage of the two eyes may have some positive effect in establishing the normal orderly matching of the connections from the two eyes.

Specificity without visual experience

The properties of neurones in the adult primary visual cortex vary greatly, but it can be said of the vast majority that they selectively respond to only a very small proportion of the vast gamut of possible visual stimuli[6]. They are selective according to (1) the position of the stimulus, (2) whether lighter or darker than the background, (3) its direction and velocity of movement, (4) its size and orientation, and (5) the disparity or relative positioning of the image in the two eyes[18,19]. All are agreed that neurones with selectivity for (1), (2) and (3) occur in very young kittens without visual experience. Hubel and Wiesel also said there were many cells with the normal selectivity for the orientation of an extended object, as well as normal binocular connections, and it was on this basis that they concluded that all selectivity was innately determined. Barlow and Pettigrew[20] and Pettigrew[21] found clear-cut selectivity for the direction of movement of a stimulus in animals with no visual experience, and thought that the apparent orientational selectivity could be attributed to this directional selectivity. This seems to be wrong, for although many of the cells in very young animals are abnormal in their selective properties, there are about 25% (refs 2, 4) with the orientational properties of adult simple cells

With regard to older, totally deprived, kittens Hubel and Wiesel again reported many normally selective cells, whereas Barlow and Pettigrew found a remarkable lack of them, and in this respect later work has supported them[2,4,22]. Even without the evidence from older kittens, however, it is now clear that all the types of selectivity of area 17 neurones, except that for binocular disparity, occur with no visual experience. The question whether they have as high a degree of selectivity as adults is still open, and there does seem to be a possible role of experience in "tuning up" their selectvities. This is a point of some interest because of the slow attainment of the high acuity characteristic of adults (*vide infra*).

Disparity selectivity

Most studies have followed Hubel and Wiesel in representing the binocular–monocular properties of cells in the visual cortex by "ocular dominance histograms". Cells are classified into seven categories varying from those excitable only through the contralateral eye (group I), through those excitable equally well by either eye (group IV), to those excitable only by the ipsilateral eye (group VII). Such histograms tell one the relative strengths of the excitatory inputs from each eye, but they tell one nothing about the way the inputs from the two eyes interact This is important, not only because of possible facilitation, summation, or occlusion, but also because the input from an eye that does not excite a neurone can nevertheless inhibit it[21]. Thus the fact that ocular dominance histograms of very young kittens resemble those of normal adults does not mean that these animals handle binocular inputs normally. Pettigrew[21] studied this aspect of the problem in developing cortex and found a marked increase in the degree of selectivity for disparity with age and visual experience. Binocular interactions of young or inexperienced neurones occurred, but were much less precise and lacked the inhibitory component prominent in older and experienced neurones. The implication is that very young and totally deprived animals have normal ocular dominance histograms, but the critical inhibitory interactions of adults develop only with experience. This deserves repetition, especially in view of the contradictions about orientational selectivity, for it is again strong evidence for a constructive role of experience in forming the connections which combine the inputs from the two eyes.

Modifiability of other properties

A controversial problem is whether properties of the population of cortical neurones other than binocular connectivity can be affected by experience. Hirsch and Spinelli[24,25] and Blakemore and Cooper[26] reported dramatic results induced by exposing kittens to striped patterns, and Shlaer[27] produced some evidence that a prism in front of one eye deviates the receptive field positions of that eye These results were extended in later reports[28,29] and since then modifications have been described as a result of rearing animals in stroboscopic light[30,31], in an evironment of moving stripes[32–35] and in a visual environment of dots without any stripes or lines[36,37]. Some of these treatments are claimed not just to modify the proportions of neurones of different types, but also to produce neurones with properties totally unlike any that are found in normal cortex. For instance Hirsch and Spinelli[25] reported units that seemed to have a receptive field exactly matching several bars of the grating the eye had been exposed to, and a close matching of receptive field to stimulus also seems to occur when kittens are raised in an environment of dots without lines[36,37]. The cortical units reported for these kittens would certainly be most unusual in normally reared animals.

Another example of abnormal units was described by Pettigrew, Olson and Hirsch[38] in the cortex of cats reared with one eye viewing vertical, the other horizontal, stripes, for they found units, like those described by Blakemore and Van Sluyters[14] following reversed suture, that had widely divergent preferred orientations in the two eyes. Again, when one eye is rotated surgically but not closed in young kittens[39], the position of the receptive fields at different points in the cortex stay unchanged relative to the retina. The orientations are not however normal: after correction for rotation the preferred orientations in the two eyes may be widely divergent in the few remaining binocular neurones. Once more we have evidence that coordinated binocular stimulation is needed to obtain coordinated developement of the appropriate selectivities.

Behavioural consequences of selective visual diets have also been described[40,41], though these are rather subtle and hard to observe compared with the effects of monocular deprivation[42,43] There have been no reports of animals or humans with supernormal visual capacities following abnormal early visual experience, though this might be expected to arise according to some views. Some failures to obtain modification have been reported but hitherto these could be explained by differences of species, as when rabbits were used[44,45], or procedure, as when Maffei and Fiorentini[46] used vertical stripes of rather limited vertical extent and exactly regular periodicity.

At this point it seemed that, although most forms of selectivity were detectable in inexperienced cortex, they were also modifiable by subsequent visual experience. The report from Stryker and Sherk[1] however, has reopened the whole issue, for they made a careful and thorough attempt to reproduce the stripe-rearing experiment, following the procedures of Blakemore and Cooper, but they were unable to obtain significant results. The main points of difference were (1) an improved method of selecting the cells to be recorded from, aimed at obtaining more representative samples; (2) the use of a computer to control the stimulus and record the results, instead of hand-moved targets and subjective impressions, (3) ensuring that the experiment was done "blind", without the experimenters knowing the rearing conditions. Many people are likely to conclude that experimenter bias, reliance on subjective impressions, and an effectively very small sample of cells explain the dramatic findings of the previous experimenters, though it is not clear whether Stryker and Sherk hold this opinion. Against this conclusion is a brief study by Pettigrew, Olson and Hirsch[34] that was done blind, with computer control, and with positive results. There are further results, as yet unpublished, from Pettigrew's laboratory, and some of the papers already quoted contain incidental confirmation of the stripe-rearing effect (see also the note added in proof to this article). Obviously one must consider Maffei's and Fiorentini's[46] negative results again, but it seems to me unlikely that so many reasonably careful people should have been fooled so much of the time, and the clinical evidence to be described below establishes that orientational properties can be modified. It is therefore worth considering other possible explanations for the negative results.

The condition of the kitten when viewing the stripes is the natural point to probe. Was it alert? How much time did it spend looking up or down, and thus deviating the lines from their intended horizontal or vertical? What else did it see? Was it hungry, interested, rewarded? All these factors are hard to control, but may be expected to influence the results if the modification is anything like those occurring during normal learning As a possible physiological explanation it is worth pointing out that Otten and Thoenen[47], studying the effect of preganglionic stimulation in inducing enzyme formation in sympathetic ganglia, had at one point great difficulty in getting reproducible results. This was traced to the glucocorticoid level in the blood at the time of induction: if the experiment was done in the morning, when the level was low, induction failed Perhaps Stryker's and Sherk's cortical neurones ignored the stripes for the apparently irrelevant reason that they were exposed at the wrong time of day Another possibility is that the sensitive period for orientational lability is earlier than that for ocular dominance, as Daw and Wyatt suggest for modifiability of directional selectivity[35] There is also some evidence that dominance changes are slower than changes of orientation[29,48]. At all events the matter is unlikely to be accepted as closed and one must hope for more conclusive experiments in the future.

Evidence from psychophysics

These contradictory results go some way towards justifying the remark of one of the founders of cortical neurophysiology: "Recording from single units gives interesting results, but they are usually wrong". He was probably referring to other people's results, but he generously went on to say, "Visual psychophysics is dull but usually right". Even though psychophysicists do not necessarily share this confidence, it is worth trying to relate the neurophysiology to measurable psychophysical function, for there is new evidence that bears on the question of cortical modifiability. This actually lends quite powerful support to the single-unit results which have been called into question.

The main factor that limits the resolution of the adult visual system, as measured on straightforward tasks such as the visibility of a grating, is the finite size and separation of the elements of the retina. In the fovea of man this limit occurs at about 50 cycles per degree, and is set by the spacing of the receptor cells[49] Away from the fovea, the minimum resolvable angle rises with eccentricity at the rate of nearly 0.5 min per degree, so that at 10° eccentricity only about 10 cycles per degree can be resolved. The limit here is probably also set by the retinal grain, in this case traceable not to receptors but to the separation of the ganglion cells that transmit details of the image centrally. In the cat it seems to be the size of the ganglion cells' receptive fields and their separation that limit acuity, even in the area centralis[50–52].

Clearly, if the fibres connecting eye to brain made very diffuse or scrambled connections one would not be able to resolve the image to a dimension set by the separation of their pick-up zones in the retinal image. These fibres must, therefore, make connections in the adult that are in some sense appropriate and orderly.

It is interesting that, for some tasks, the full resolution available from the retinal mosaic seems not to be used. Andrews, Webb and Miller[53] investigated the accuracy with which length comparisons could be made when the markers to indicate the lengths lay up to 5° from the fovea After allowances have been made for eccentricity, the grain size that would be sufficient to enable this task to be performed was about 10 times larger, measured linearly, than that required for grating resolution. They made the interesting suggestion that this coarser mosaic is determined, not in the retina, but in the primary visual cortex, where it could correspond to the dimension, projected into the visual field, of the repeating subunit called a "hypercolumn" by Hubel and Wiesel[54,55]. This is the area of cortex, about 1 or 2 mm square, within which a complete cycle of ocular dominance is contained when moving across the cortex in one direction, and a complete cycle of orientational selectivity when moving in the orthogonal direction. It is thus a unit cell containing all orientation selectivities and all degrees of ocular dominance. Although the receptive fields of successive units isolated on moving an electrode across a hypercolumn show an average tendency to move across the visual field in the manner predicted from the overall mapping, an exact progression is not found[55,56]; the units are scattered around the expected positions in an apparently random manner, so it seems that the topographical orderliness for retinal position has been replaced by orderliness for orientational selectivity and ocular dominance On the hypothesis being advanced, the output from a hypercolumn carries the information as to which hypercolumn is involved, but no information about position within it, and the consequent discarding of information causes the loss of resolution for the type of task Andrews *et al.*[53] studied.

Another task that suggests massive reduction of positional information is the counting of narrowly spaced lines that has been studied recently by Atkinson *et al.*[57]. They found that subjects started to make serious errors in counting even small numbers of lines when these are crowded close together: possibly the output from a hypercolumn can only signal "one" or "many", and for exact counting the lines in the target must fall on separate hypercolumns.

Thus, some tasks seem to be limited by the retinal grain, others by a coarser grain that may correspond to the hypercolumnar structure of the primary visual cortex. There are yet other tasks which at first seem to demand an even greater degree of precision than grating acuity. These are tasks like detecting the displacement of a vernier, the curvature of a line, or comparing the disparity of a pair of lines, and their common feature is that they require the detection of the relative positions of features in the stimulus that lie close to each other in the visual field. Since they are close, they could be within the area of visual field covered by one hypercolumn, and this type of information about relative position is not discarded, but jealously preserved. The precision with which these tasks can be performed is extremely high, of the order of a few seconds of arc, but Andrews, Butcher and Buckley[58] show that this is no higher than the accuracy expected from efficient use of the information in an image limited by the retinal grain The improvement results from averaging, and simply corresponds to the fact that a mean is more precise than the individual measurements on which it is based. Thus there is no mystery about how the information required for the task gets to the brain, but a highly precise and orderly arrangement does seem to be required in order to extract it, and this is presumably one of the tasks of the hypercolumns in the primary visual cortex.

To summarise, then, psychophysics suggests there must be precisely ordered connections from eye to brain to preserve details down to the size of the retinal mosaic, and an even more precisely ordered arrangement within V1 for extracting the relative mean positions of features present in the image. But there is nothing impossible or implausible in these requirements, for hypercolumns are 1 or 2 mm across and contain some 10^5 cells, which allows plenty of scope for the operations demanded. The next step could be a reduction of positional information in the visual message brought about by retaining information about local pattern or relative position, but discarding absolute positional information, thus simplifying the picture by coarsening the mosaic to that of the hypercolumnar structure of V1.

Precise, orderly, and appropriate functional neurone–neurone connections are the essence of these operations. If they are made once and for all and are not modified or varied in potency by visual experience one would have a visual system whose performance depended exclusively upon its innate connectivity, a model sometimes referred to as the "hard-wired" cortex. A hardline advocate of hardwiring will explain effects of experience exclusively in terms of disruption of innate connections, but arguments can be made on general grounds for a more constructive role. Platt[59] for instance held that a precision of a few seconds of arc could not possibly be laid down under genetic instruction, and would be hopelessly inflexible even if it could be. Andrews[60] argues that experience must be important in determining the metrical properties of perception, and Blakemore and Van Sluyters[2] suggest that experience ensures the alignment of the contributions from each eye to binocular receptive fields. Although these ideas are interesting they are not by themselves fully convincing. A teleological argument from the very existence of the sensitive period carries some weight, for it really is hard to believe in the survival value of a period of pure disruptibility, whereas a period of refinement and adjustment by experience would make good sense. At the moment there are no hard facts establishing such a role, but new evidence shows where the case for hardwiring is incomplete, and hints where visual experience may have its effects. Furthermore, recent experiments on the transfer of after effects support some of the concepts relating to cortical neurophysiology and psychophysics that have been discussed in this article.

Development of visual acuity

The neurophysiological argument for an innately connected cortex rests on the presence of selectively sensitive neurones in young, visually inexperienced kittens and monkeys One could rule out any role of experience if such animals had full adult acuity, but this is far from the case. Acuity develops rather slowly in kittens[61,62], and does not reach its full adult value until quite late in the sensitive period. This could be a matter of removing other impediments to resolution, and as in all behavioural experiments one cannot be sure that the kitten is making full use of his sensory mechanisms, but the behavioural result is here supplemented by the study of cortical evoked potentials[61]. In humans too it seems that acuity is poor in young infants[63,64] and reaches a value comparable with that of the adult long after the system seems to be optically efficient

One would like to know more about the effects of early binocular deprivation on visual capacities after sight is restored, for clearly if full acuity can ever be found in an animal that has been totally vision-deprived up to the moment of testing, this would rule out any important role for experience in performing resolution tasks. Clinical evidence on this is not very conclusive[65–67] and results on animals are not yet very extensive[43,61,62,67] but it does not seem that full visual capacities ever mature without considerable experience, and they often fail to do so if the experience occurs after infancy. If full performance cannot be achieved without experience, the implication is that normal experience aids cortical development and does not merely fail to hinder it.

Meridional amblyopia

The starting point of this whole enquiry was the fact that an eye can become blind when it is in competition with the other, functionally superior, eye, and the discovery that a similar condition occurs in cats and results from changes in the connections of cells in the primary visual cortex It has long been recognised clinically that individuals with severe, long standing, astigmatism often fail to achieve good resolution in the affected meridian, even with the best correction of the optical condition. Testing the acuity of such subjects by generating interference patterns directly on their retinae has ruled out the possibility of a residual optical defect, and has now shown that this "meridional amblyopia", as it is called, is really of neurological origin[69]. Kittens reared wearing goggles containing cylindrical lenses have been shown to lack cortical neurones tuned to the blurred meridian, thus completing the cycle of evidence[70].

In spite of the difficulties in repeating the original stripe-rearing experiments, this clinical condition seems to establish beyond any reasonable doubt that the orientational properties of cortical neurones can be influenced by experience, though it does not of course establish that the changes are as described in the original neurophysiological experiments

Stereo blindness

Strong neurophysiological evidence for a positive role of visual experience in setting up the visual cortex was given by Pettigrew's finding that cells narrowly selective for a particular disparity are not found in kittens that have had no binocular visual experience The high incidence of anomalies of stereoscopic vision is therefore intriguing. Richards[71] estimates that 14% of the population lack the full ability to use binocular disparities to judge depths, and he reports interesting evidence that the stereo blind may fall into at least two classes—those who cannot use the convergent disparities of objects closer than the fixation point, and those who cannot use the divergent disparities of objects lying further away than the fixation point. Now phorias, or tendencies to strabismus, are common in infancy, and could cause deprivation of binocular stimulation. If the phoria is of the convergent variety, objects at the attempted fixation distance will have divergent disparities, but the system will tend to be starved of convergent disparities. Similarly those with a divergent phoria will be exposed to convergent disparities but will tend to be deprived of exposure to divergent disparities. The two forms of stereo blindness could thus be other examples of deprivation amblyopia

Recent clinical evidence suggests that a week of monocular deprivation in infancy can lead to unilateral amblyopia in later life[72,73], so the sensitivity to deprivation is certainly very high in humans. The more subtle role of phorias in causing stereo blindness seems to be another potentially fertile field for correlating neurophysiological and clinical results.

Transfer of after effects

The view that proper stereopsis depends upon experience is supported by recent experiments comparing the transfer of after effects in normal adults and those who have seriously impaired stereoscopic vision, but have good monocular vision in both eyes, and no diplopia. From the cortical neurophysiology one might hazard a guess that they do not have disparity selective cells in area 17, and probably possess a population of neurones like that found after strabismus or alternating occlusion in kittens: that is, many cells monocularly dominated from each eye, but very few that receive binocular connections. Now there are a number of illusions such as motion after effects, tilt after effects, and distortions in the appearance and threshold modulation of gratings, that are commonly attributed to fatigue of cortical neurones; Maffei, Fiorentini, and Bisti[74] have recently shown that such fatigue does occur. Furthermore, such illusions normally transfer from one eye to the other, so that if the fatiguing stimulus is given to one eye, the illusion can be detected when that eye is closed and the other eye opened. Now if stereoblind individuals lack binocular neurones, such transfer should be impossible, and that is precisely the result that has been found[75–78]. In an ingenious application of this finding Hohman and Creutzfeldt[79] have concluded that the sensitive or labile period for development of binocular neurones in humans extends to the third year.

It is interesting that Ganz, Hirsch and Tieman[80] found normal interocular transfer of learned pattern discrimination in cats reared with alternating occlusion of the two eyes and therefore presumably possessing very few binocular cells in their primary visual cortex. This result does not conflict with the absence of transfer of after effects in such a cortex, because the tasks performed are so different. The persistence of transfer of learned discriminations presumably means that they were performed at a level where information as to which eye provided the image had been discarded.

Conclusions

The neurophysiological experiments that have helped so much in understanding the normal and abnormal development of the visual cortex are difficult and arduous to perform. The preparation involves several hours of surgery, and this is followed by a prolonged period of recording during which the animal has to be maintained lightly anaesthetised and in excellent condition. Worthwhile results are rarely obtained in less than 16 h, and recording often continues round the clock for 48 h or more. On top of this there are the frustrations and difficulties of maintaining cats in colonies that are notoriously liable to obliteration by epidemics. In view of this it is not the controversy but the agreement with Hubel and Wiesel's results that is surprising, and we owe to them most of our knowledge of the visual cortex as a precisely arranged structure laid down before visual experience, and thus innate. A good deal has, however, been added to their picture, and this shows it is not really established that all is innate. First, neither an inexperienced animal, nor an inexperienced neurone, has been shown to have the normal powers of resolution, and selectivity for disparity especially seems to require experience. Second, there is the evidence that experience after monocular deprivation causes the construction of a differently organised cortex. Third, Cragg[3] has recently published evidence showing that less than 1% of synapses in primary visual cortex develop before eye-opening, and hence there is, if Hubel and Wiesel are correct, an embarrassing difficulty in explaining what the other 99% do! But this merely underlines the disquieting fact that we do not fully understand what part area 17 plays in vision—itself another reason for caution in making pronouncements upon the relative importance of innate and experiential factors in creating the intricate mechanisms that underlie our visual capacities.

There is so much to be explained in the formation and adjustment of the connections between the 10^9 or so cells of our visual cortex that it is perhaps time to abandon the idea that nature and nurture are rivals at this task. That is too simple a view; instead one should suspect that they work in collusion, and seek how and where this may occur. Does the nervous activity from experience influence the survival and effectiveness of excitatory synapses? Does it exert its effect on the pattern of connections of an intrinsic inhibitory system that is established after the innate excitatory one? Or is there an interaction between nervous activity and the development process itself, as seems to occur in goldfish tectum[81]? The evidence reviewed here suggests that some of the answers are still waiting to be found in the mechanisms of the primary visual cortex that analyse details of the image and combine the information from the two eyes.

Note added in proof: Three new twists must now be added to the story on the effects of selective exposure First, Hirsch and Levental[82] report more experiments in which kittens were reared wearing goggles of the type used in the original experiments of Hirsch and Spinelli[24,25] In their new experiments the eyes viewed stripes within the goggles that were either left oblique for one eye and right oblique for the other, or horizontal for one eye and vertical for the other as in the original experiment For the latter condition they confirmed, using more conventional neurophysiological techniques, that cells selective for horizontal orientations were almost all connected only to the eye that had viewed horizontal stripes, and similarly for the vertically orientated cells. There were a few cells which broke this rule by responding to verticals through the horizontally exposed eye and vice versa, but there were no cells at all that responded to oblique lines. The animals reared viewing obliques had many obliquely sensitive cells connected to the appropriate eye but also had many cells which responded to horizontal or vertical stripes through each eye They conclude that genetic factors are sufficient to develop horizontal and vertical orientational selectivity, but that experience is required for the obliques.

The second twist is a note added to Stryker's and Sherk's paper[1] confirming these results for kittens reared with the horizontal/vertical goggles, using their more precise quantitative techniques. It is not yet known whether the differences between the results using goggles, and those from Blakemore's and Cooper's cylinders, is due to more effective control of the visual experience, or whether the conflicting experience of the two eyes in the goggles is the critical factor.

Finally, Grobstein and Chow[83] have reviewed their own work on the development of cortical specificity in the rabbit, and have also covered much of the material in this article. Their general conclusion is that individual sensory experience is a creative factor in establishing the functional organisation of the mammalian visual system, though they believe it affects the rate of development more than the end state reached.

New evidence regarding the Quaternary geology, archaeology and hominids of Chesowanja, Kenya

W. W. Bishop & M. Pickford

Department of Geology, Queen Mary College, University of London, UK

A. Hill

National Museums of Kenya, Box 40658, Nairobi, Kenya

Deposits yielding australopithecines, other fossil mammals and an industry recalling the Oldowan are succeeded by an Acheulian assemblage, overlain by flood plain silts with abundant spreads of later artifacts. The structure is dominated by an asymmetric anticline. Palaeoenvironments are reconstructed and the nature of the raw materials and of the tool makers themselves are briefly discussed.

CHESOWANJA is a Pleistocene fossil and artifact locality in the Northern Rift Valley of Kenya, about 1.5 km west of the track between Mukutan and Tangulbei, at 36° 12′ E, 0° 39′ N, and 8 km WNW of the point at which the Mukutan river gorge cuts through the Laikipia Escarpment. A diverse fauna includes the partial cranium of a robust australopithecine[1,2].

We report here results from more detailed geological mapping in 1973 and 1974. A remarkable sequence of artifact-bearing levels has been discovered together with a further hominid. The original geological interpretation has been shown to be in error, necessitating re-assessments of the local stratigraphic relationships, the palaeoenvironmental setting and the age of the sequence.

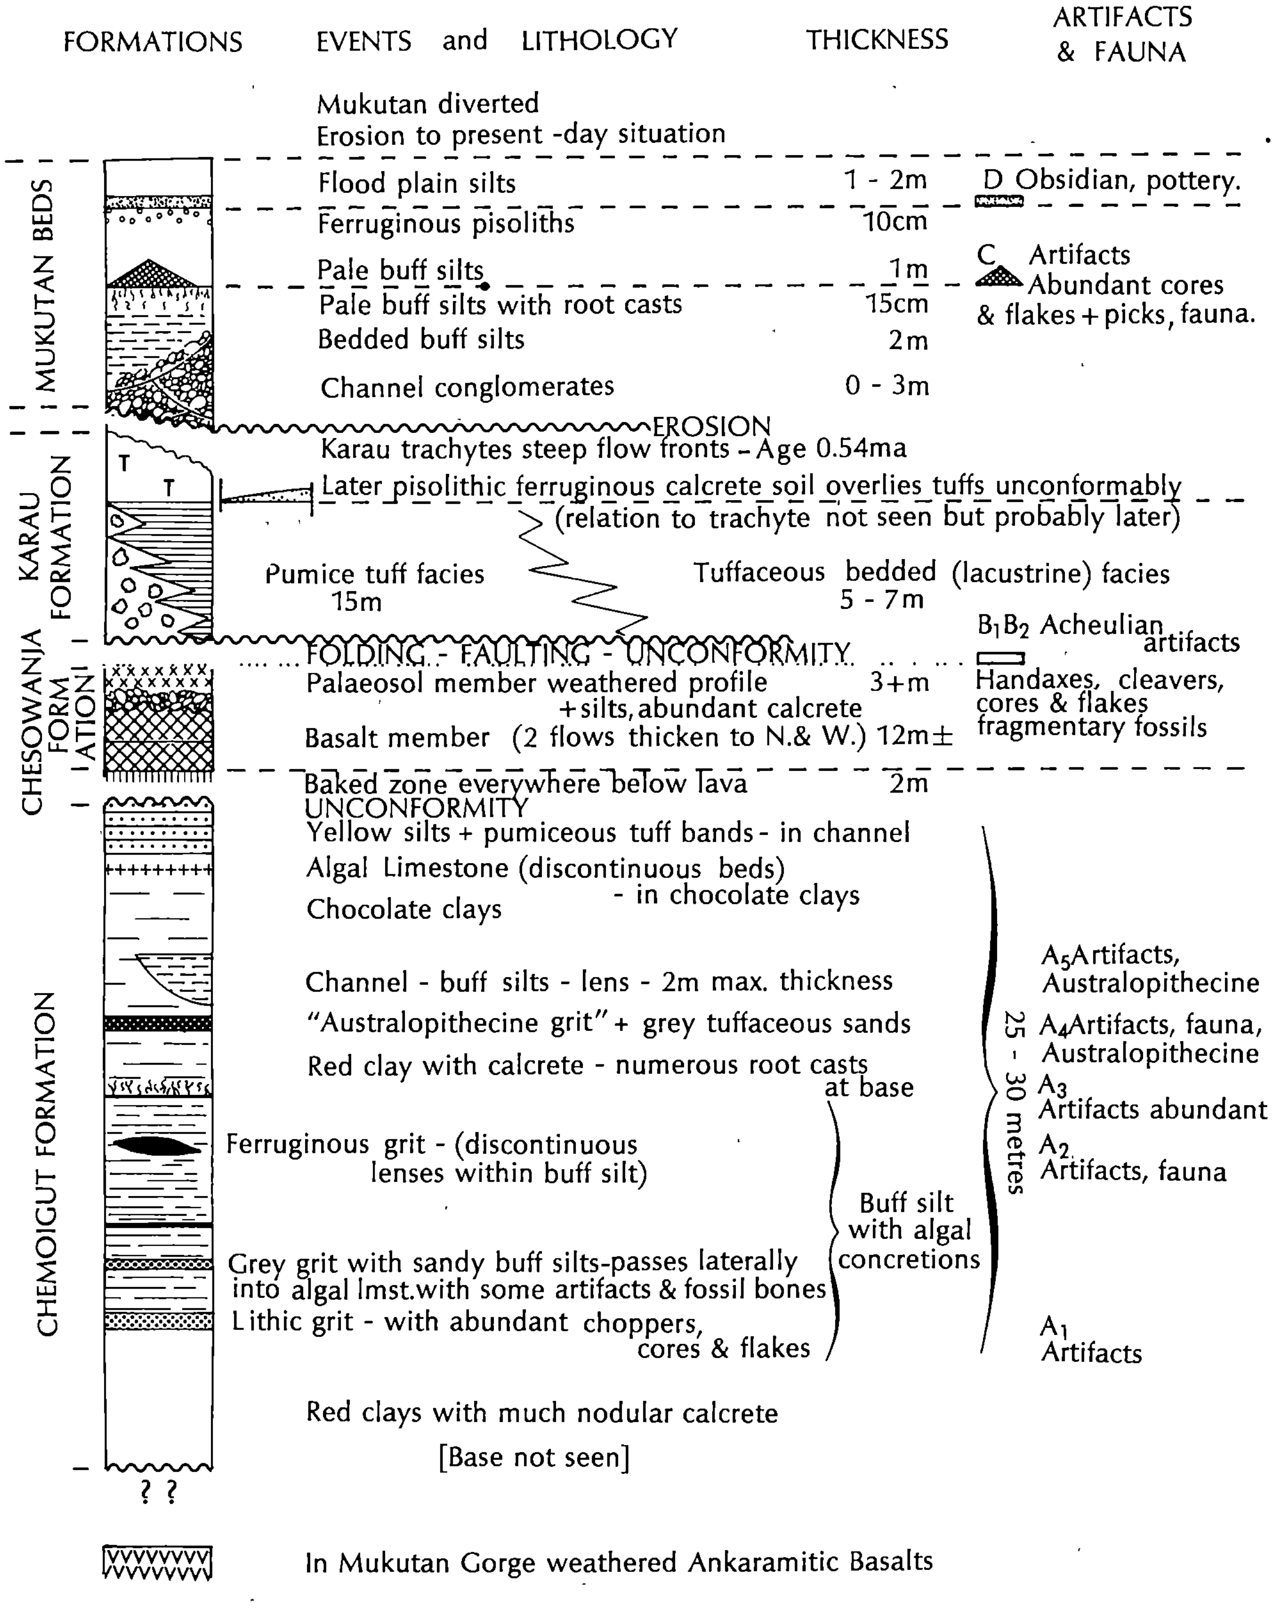
The area is important because the succession of rich artifact assemblages, from a relatively small and well defined region, spans a period probably well in excess of a million years. The associated geology and fossil fauna enable palaeoenvironmental contexts to be inferred for the various phases of hominid activity.

Geological succession

The local sequence of strata (Fig. 1) comprises four lithological units: the Chemoigut Formation, Chesowanja Formation, Karau Formation and Mukutan Beds. Formal descriptions of these and of the geology of the surrounding area will be published elsewhere.

The Chemoigut Formation consists of a sequence of silts and clays with intercalated horizons of coarse tuffaceous and pumiceous sandstone and fine conglomerate. There are calcareous bands and concretions, some of which are of algal origin, and thin flaggy and nodular calcrete horizons, several containing abundant root casts. There is also evidence of channelling. The observed thickness of the unit is ~ 25–30 m. The succession overlies red clays containing nodular calcrete, which elsewhere rest on very weathered ankaramitic basalts.

Artifacts have been found eroded out at a number of different sites from at least five horizons. Australopithecine remains come from the two highest levels. The fauna is listed in Table 1.



FORMATIONS
EVENTS and LITHOLOGY
THICKNESS
ARTIFACTS & FAUNA
Mukutan diverted
Erosion to present -day situation
MUKUTAN BEDS
Flood plain silts 1 - 2m
D Obsidian, pottery.
Ferruginous pisoliths 10cm
Pale buff silts 1m
C Artifacts
Abundant cores & flakes + picks, fauna.
Pale buff silts with root casts 15cm
Bedded buff silts 2m
Channel conglomerates 0 - 3m

In Mukutan Gorge weathered Ankaramitic Basalts

Fig. 1 Sequence of strata exposed in the Chesowanja area

The Chesowanja Formation includes a basalt member composed of two flows, the lower of which is more fissile, and has baked and reddened the upper 2 m of the underlying Chemoigut Formation. It varies from 5 to 10 m in thickness. The upper flow is about 6 m thick. The surface of the upper flow is deeply weathered and large core stones of basalt occur at the base of a palaeosol complex 3 metre thick (palaeosol member, Fig. 1) containing abundant calcrete concretions. An assemblage of Acheulian artifacts with a sparse but persistent accompaniment of fragmentary fossil material occurs at the upper surface of the formation.

In the west, the lower sediments of the Karau Formation are coarse pumice tuffs about 15 m thick, which lie unconformably over the Chesowanja Formation. The pumice tuffs can be equated with 5 to 7 m of fine tuffaceous, well bedded sediments in the east that show graded and current bedding. These seem to represent a penecontemporaneous lacustrine facies of the pumice tuffs. The upper member is the Karau trachyte which exhibits steep flow fronts to the west of the main fossil and artifact localities.

The Karau Formation lies under local unconformities in the vicinity of the artifact and faunal areas; elsewhere it lies under a thin but persistent weathered horizon which has a patchy distribution and is characterised by ferruginous pisoliths. (see Fig. 1).

In the eastern part of the area the Karau formation is overlain by Mukutan Beds, a laterally extensive succession of channel conglomerates and silts approximately 8 m thick. The best exposures are in the Losokweta river valley and along the sides of the abandoned channel of the Mukutan River. Artifacts and fauna occur abundantly along this former course of the Mukutan.

Geometry of the units

The local relationship between the lithological units is shown in Fig. 2. The Chemoigut and Chesowanja Formations are folded into an asymmetric anticline, the axis of which trends north–south. The inclination of the beds on the western limb is about 11°. On the east they are inclined more steeply, and dips in excess of 60° are typical. The characteristically spheroidal weathered top of the upper basalt flow has been seen at only two points.

The Chemoigut sediments are exposed within the core of the anticlinal structure in three windows, each approximately 200 m across from east to west. The three windows have a total outcrop length of about 1 km from north to south along the main axis of the anticline.

Horizontal strata of the Karau Formation rest unconformably upon the flanks of the anticline indicating post-tectonic deposition. The absence of *in situ* material of this formation resting on Chemoigut sediments suggests that the Karau Formation was deposited before the fold structure in the basalts was breached. The upstanding form of the anticline at that time may account for the differing facies of the rocks on the east and west of the feature assigned to the tuffaceous member of the Karau Formation.

The more recent Mukutan Beds crop out patchily over an extensive area to the east of the Losokweta River, where they lie under the westerly sloping pediment and wash plain at the foot of the Laikipia Escarpment.

Another hominid

The partial cranium of a robust australopithecine (KNM-CH-1) reported previously[2], came from the unit now called the grey tuffaceous grit within the Chemoigut Formation. More hominid fragments were found in 1973, belonging to another individual (KNM-CH-302). They came from within chocolate clays of the same formation (see Fig. 1) some 3 m higher in the sequence than the original cranial fragment. Although the fragments are surface finds, the local topographic situation (an isolated clay spur yielding fresh artifacts) suggests that they were not far removed from their original position.

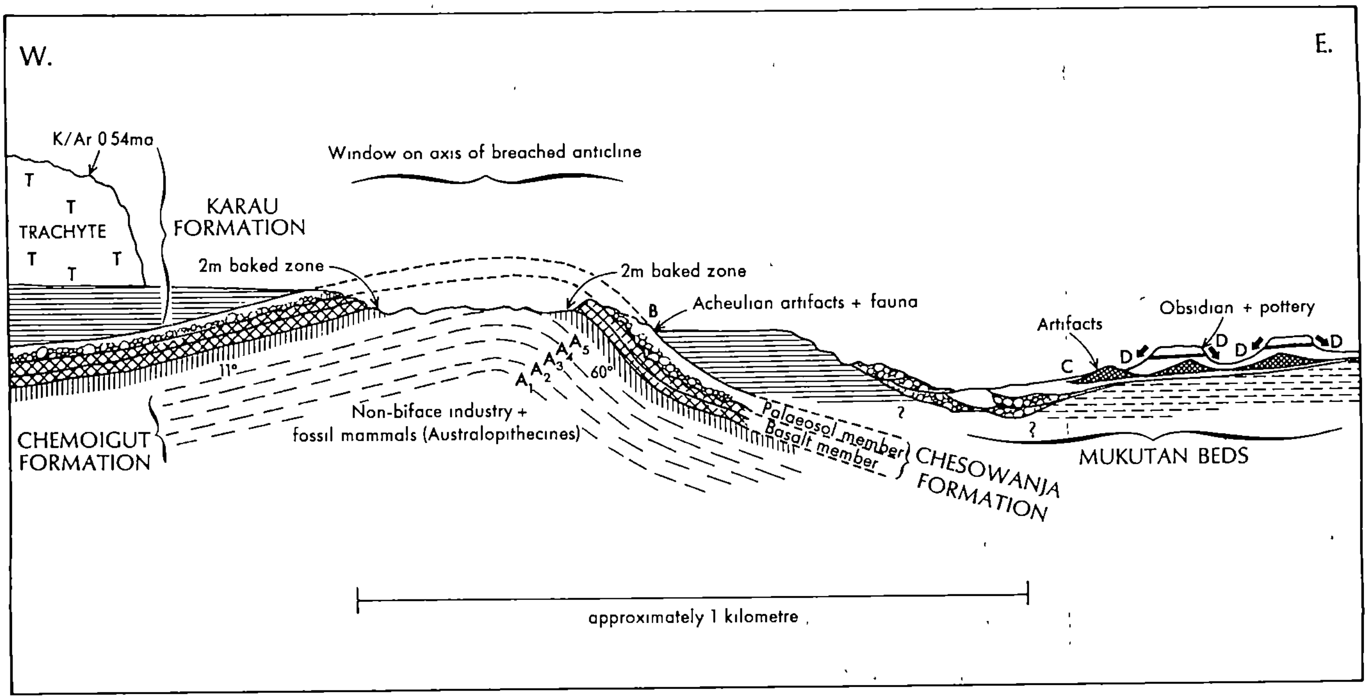
The specimens consist of a number of fragments of two molar teeth, probably of the same individual. One is a fragmentary right M^1 or M^2 crown showing features typical of the dentition of robust australopithecines. From the material available it is impossible to ascertain the exact dimensions of the tooth.

Archaeology

Archaeological material comes from at least eight levels within the vertical sequence of some 50 m of sediment and lava already described. All the occurrences are within about 1 km of each other. From their stratigraphic setting the artifacts can be assigned to four age groups, indicated as A_1, A_2, and so on, B, C, and D (Figs 1 and 2).

Group A. These assemblages of cores, chopping tools and flakes without bifaces and cleavers are confined to the Chemoigut Formation. They occur on at least five levels, including those from which the hominid specimens and other mammalian fossils also come. The five artifact-bearing levels have at least ten rich sites from which associations of artifacts are being eroded. No excavations have yet been undertaken but small samples from four of the sites have been collected. The 220 pieces include: 17 choppers; 8 polyhedrons; 4 discoids; 3

Fig. 2 Diagrammatic section across the Chesowanja area showing relationships between lithological units (not to scale). (We thank Dr Mary Leakey for the comment that the 'non-biface industry' may prove to be Developed Oldowan.)



protobifaces; 6 scrapers; 5 sundry tools; and 177 samples of waste, debitage, flakes, and so on. In spite of a detailed search no obvious hand axes or cleavers were found within the Chemoigut Formation windows, although they are abundant in group B.

Group B. An Acheulian assemblage with bifaces, cleavers, cores and flakes, comes from the surface of the palaeosol member. The latter is a complex weathering profile developed on the upper flow of the basalt member of the Chesowanja Formation, on the eastern limb of the anticline. At another locality on the same horizon small flakes and cores are dominant. A rather different, younger assemblage of artifacts occurs in association with the weathered horizon containing ferruginous pisoliths.

Group C. A third group of artifacts comprises mainly large cores with piles and spreads of associated flakes, together with occasional bifaces showing an economy of flaking technique, double ended picks, and beaked implements recalling the type 'Sangoan' in morphology[3,4]. Very large local accumulations of this material are found at numerous tool sites along the dry river bed marking the former course of the Mukutan. They are being re-excavated from the pale buff silts comprising the former flood plain of the Mukutan by modern stream action and sheet erosion.

Group D. Obsidian flakes and pottery occur intermingled with debris of group C. They seem to be eroding out from an horizon characteristerised by the presence of ferruginous pisoliths, stratigraphically a little above the level of assemblage C within the Mukutan Beds.

More recently, the river Mukutan has been diverted for irrigation purposes. Wood from a burnt stump of a large tree along the abandoned channel has yielded a radiocarbon date of 230 ± 110 yr b.p. (unpublished, Birmingham University Radiocarbon Laboratory Date BIRM 537).

Age

In the original publication[2] and in later comments[5,6] it was suggested that the sediments now placed in the Chemoigut Formation were probably younger than 1.2 Myr, but it was stressed that this estimate depended for its accuracy on the geological interpretation. Subsequent work has shown that the relationship of the Chepchuk trachyte (from which the 1.2 Myr date was obtained) to the fossiliferous sediments is not yet established.

The fauna from the Chemoigut Formation (Table 1) is not inconsistent with the original assessment. The *Deinotherium bozasi* Arambourg from the formation would, however, be the youngest known if the K–Ar age of less than 1.2 Myr were accepted. This may prove to be the case, but until additional isotopic dates are available the faunal evidence suggests an age for the formation in excess of 1.34 Myr, which is the date of the latest *D. bozasi* recorded elsewhere (below tuff J, Shungura Formation, Omo[7]).

Palaeomagnetic measurements on material from the baked zone of the Chemoigut sediments lying immediately under the Chesowanja basalt member indicate a reversed polarity (A. Brock, personal communication) and preliminary readings suggest that other levels in the Chemoigut Formation are also reversed (P. Dagley, personal communication). Taking other evidence into consideration, this would place the age of the basalt and the underlying sediments in the Matuyama Reversed Epoch between about 0.7 and 2.4 Myr BP.

The Chesowanja Formation is overlain by the Karau Formation, and a ^{40}K–^{40}Ar age determination on the Karau trachyte has given a date of 0.54 Myr BP. Micas within the tuffaceous member of the Karau Formation in its lacustrine facies, are also potentially dateable. Preliminary palaeomagnetic measurements of the tuffaceous member have produced a number of normal readings (P. Dagley, personal communication).

Palaeoenvironment

The artifact assemblages of Group A have not yielded examples of hand axes or cleavers. They lie under and predate the typical Acheulian elements of group B and thus invite comparison with the 'non-biface' Oldowan Industry at Olduvai Gorge. The sediments of the Chemoigut Formation indicate an environment on the margins of a saline lake with a fluctuating water level. Several fresh cores and flakes have a calcium carbonate encrustation of algal origin. It is interesting that the Bed I and lower Bed II Oldowan assemblages of Olduvai also occur around the margins of a saline lake[8].

The Acheulian of group B is from a subaerial environment on the upper surface of a complex weathered profile. The artifact sites lay to the east of an anticlinal ridge at the foot of a pronounced basalt feature caused by the sharp flexure forming the eastern limb. A lake may have existed only a short distance further to the east as the Acheulian surface is overlain by well bedded, tuffaceous strata, indicating deposition in standing water. A sudden local rise in the water level would have occurred with the influx into the catchment area of large amounts of pumiceous ash from the trachyte centre of Karau which lies 4 km to the South-west.

The piles and spreads of artifacts in group C represent stone working sites and occur upon root cast surfaces in flood plain silts. Adjacent fresh flakes can be fitted together on to the large cores from which they were struck. The industry was based on raw material of phonolite cobbles from anastomosing water-courses of the former Mukutan river system. The artifacts were stratified beneath flood plain silts and wash deposits as the local base level rose. Local breaks in sedimentation occur. One of the most pronounced of these is marked by ferruginous pisoliths. Microlithic tools and flakes in obsidian and other lithologies, together with pottery, were stratified during this phase of flood plain deposition which culminated some 2 m above the horizon of group C. Later incision initiated a cycle of erosion which is still continuing and has produced remnant mesas (Fig. 2). This cycle has re-excavated broad channels to below the level of group C and has produced an intermixing, on the present day surface, of elements of groups C and D, together with occasional implements in iron The exact relationship of these artifacts will only be established by careful excavation of *in situ* material.

The main flow of the Mukutan river was diverted towards the north by the Njemps tribesmen 100 or more years ago to irrigate the wash plain for agriculture.

Raw materials

An ongoing study is concerned with identification of the various rock types used by makers of the tools in groups A–D. The earliest tool kits reveal great petrological variety including different trachytes, phonolites and welded tuffs, together with occasional basalts. The Acheulian raw materials of group B are restricted to trachyte with some phonolite and a few small pieces in welded tuff. Group C is almost entirely based on water rounded blocks and cobbles of phonolite.

Various volcanic rocks occur in the area, surrounding the artifact sites. Thus it is possible to carry out petrological and geochemical investigations, including trace element analyses, to identify the source rocks of the artifacts. This will permit an estimate of the minimum ranges over which the early stone technologists travelled to collect their raw materials.

The fact that two more individuals of robust australopithecines have been found from horizons yielding abundant artifacts (others are known from Olduvai Gorge and East Rudolf), poses the question: "Who made the tools?"

This work forms part of a programme of research financed by the Natural Environment Research Council, the Boise Fund of the University of Oxford, the Wenner-Gren Foundation, New York, and the L. S. B. Leakey Foundation. We thank Dr S. Weaver, and R. Foley for help with field work and Dr Mary Leakey for valuable discussion. Assistance in the field also came from Mr and Mrs A. Cooper and Mr M. Fulton. The Kenya Ministry of Natural Resources made research permits available, and Mr R. E. F. Leakey and the Trustees of the National Museums of Kenya provided facilities in Nairobi. J. W. K. Harris of the Department of Anthropology, University of California provided a preliminary analysis of the samples from group A.

Significance of autogenously regulated and constitutive synthesis of regulatory proteins in repressible biosynthetic systems

Michael A. Savageau

Department of Microbiology, The University of Michigan, Ann Arbor, Michigan 48104

The functional implications of the different modes of regulation have been examined systematically. The results lead to certain predictions. The regulatory protein in repressor-controlled systems is constitutively synthesised. In activator-controlled systems synthesis of the regulatory protein is autogenously regulated. There is favourable agreement between these predictions and published experimental evidence.

REGULATION of specific enzyme synthesis has been most thoroughly characterised in the inducible catabolic systems of enteric bacteria[1,2], and in the temperate bacteriophage λ (ref. 3). Regulation of enzyme synthesis in the biosynthetic systems of bacteria has remained more obscure. Among studies on systems of the latter type, those on the tryptophan biosynthetic system in *Escherichia coli* are probably most advanced. Regulation of this operon clearly involves the classical mechanism proposed by Jacob and Monod[4]. Trytophan, the end product of the pathway, is a corepressor that can combine with an aporepressor molecule to form a "repressor" that binds to the tryptophan operator and blocks transcription[5–10]. Arginine regulation in *E. coli* may also involve a classical aporepressor[11,12], although the evidence is less extensive.

In contrast to the tryptophan and arginine systems, there is no evidence of a classical aporepressor for the histidine and isoleucine–valine biosynthetic systems, although these systems also have been investigated extensively. Consequently, basic assumptions about repressor function have been re-examined critically and other mechanisms have been proposed.

Histidyl-tRNA, rather than histidine itself, has been clearly implicated in repression control of the histidine operon in *Salmonella typhimurium* (see review by Brenner and Ames[13]). Ames and his coworkers[13–15] suggested that a complex of histidyl-tRNA synthetase (aporepressor) and aminoacylated tRNA^{His} (corepressor) may be a repressor of the histidine operon In contrast to this suggestion that the synthetase is a negative element in control, Wyche *et al.*[16] reported evidence that the synthetase is a positive element. There is evidence for yet another type of model in which the first enzyme in the histidine biosynthetic pathway (N-1-[5′-phosphoribosyl] adenosine triphosphate: pyrophosphate phosphoribosyltransferase, EC 2 4.2.17) has a role in repression control. Goldberger and coworkers[17–19] proposed that the first enzyme acts as a negative element in the control. But involvement of the first enzyme as a positive element in the control of the histidine operon also has been suggested[19,20].

These and other possible models now can be tested with purified (or partially purified) components in an *in vitro* transcription system and in a coupled transcription–translation system Blasi *et al.*[21] reported that the first enzyme blocks *in vitro* transcription of the histidine operon but, surprisingly, histidyl-tRNA was not required for this result. In contrast, Artz and Broach[22] obtained evidence that a positive element is required for expression of the histidine operon in the coupled transcription–translation system. Their studies also suggest that transcription of the histidine operon requires translation of its specific mRNA. One of several explanations consistent with these observations is that translation produces a positive factor required for transcription[22]. Thus, the results so far from these *in vitro* systems are consistent with the notion that a product of the histidine operon is involved in regulating its own synthesis. In one case, however, this product is thought to be the first enzyme and a negative element in control, whereas in the other, this product is an unspecified positive factor. A combination of the two is also a possibility.

Similar developments have occurred in the study of the isoleucine–valine (*ilv*) biosynthetic system. This system involves multivalent repression[23,24] in a branched set of pathways[25] and is, therefore, more complex than the histidine system. As is the case for the histidine operon, no classical aporepressor has been identified for the isoleucine–valine system. On the basis of biochemical data Hatfield and Burns[26] suggested a model of repression control for the *ilvADE* operon in *S. typhimurium* that involves the first enzyme of the isoleucine pathway (threonine deaminase, EC 4 2.1.16), leucyl-tRNA, valine, threonine and isoleucine. According to this model, which now has been modified and extended to cover regulation of the other *ilv* operons in *E. coli* and *S. typhimurium*[27], the first enzyme is an aporepressor and the multivalent corepressors are isoleucyl-tRNA, leucyl-tRNA and valyl-tRNA. On the other hand, Levinthal *et al.*[28] have described a regulatory mutant of *E. coli* in which the expression of the *ilvADE* operon is diminished and unresponsive to variations in the branched chain amino acids. This phenotype results from a single point mutation in the structural gene for the first enzyme of the isoleucine pathway. Based on these and other genetic results, Levinthal *et al.*[28] suggested that the first enzyme is a positive element controlling expression of the isoleucine–valine system.

A defective transducing phage harbouring the *ilv* genes[29] is being used for *in vitro* transcription and coupled transcription–translation assays, to study the molecular events in the regulation of the isoleucine–valine biosynthetic system of *E. coli*.

As this brief introduction indicates, there are repressible biosynthetic operons whose regulation involves a classical, constitutively synthesised aporepressor. There also are examples of such systems that involve autogenous regulation, whereby a regulatory protein directly modulates expression of its own structural gene[30]. Although in no case has it been demonstrated that either of these is the sole mechanism of control, the question arises: what are the functional implications of these two established modes of regulation? This question cannot be answered by comparing directly two representative systems (for example, tryptophan and histidine) because there may be still other elements involved in their control and because the systems are different in many ways that are irrelevant to a comparison of the two modes of regulation *per se*. An answer requires a more controlled comparison in which the two systems are identical in every respect except for the difference in a regulatory mechanism. This is difficult to do experimentally. At present a more practical approach is to compare mathematically models that accurately represent the different types of regulation. Such comparisons have been made and the details, unnecessary here, are available[31]. Before presenting the results it will be useful to enumerate the criteria for functional effectiveness that have been used in comparing the various models.

Criteria for functional effectiveness

Just as numerous chemical and physical criteria make possible characterisation of the molecular components of biological systems, well defined criteria make possible characterisation of the functional behaviour of an integrated system. For simplicity, in the analysis that follows I deal specifically with the regulation of unbranched pathways for the biosynthesis of amino acids. The following criteria for functional effectiveness can be formulated for these systems. It should be noted that none of these criteria assumes anything about the type of regulatory mechanism involved.

(1) Minimisation of the change in the level of end product as it shifts from one steady state to another in response to a change in demand for end product. This implies that the end product will not be depleted to such an extent that its rate of utilisation is limited when the demand is increased.

(2) Responsiveness to change in the availability of initial substrate. This is essential for the redistribution of common intermediary metabolites that occurs in response to a changing environment when the available carbon is limited.

(3) Reduction of enzyme synthesis when the end product is supplied exogenously. Since the biosynthetic enzymes become superfluous when the end product is available preformed in the environment, the importance of this criterion for cellular economy is obvious.

(4) Stability. Presumably one of the prime functions of pathways synthesising amino acids is to provide a relatively constant supply of their end products for protein synthesis. An effective system would not oscillate wildly, starving the organism for end product during one phase and overproducing and wasting it in the next. The impaired growth of mutants exhibiting such instability is readily apparent[32].

(5) Temporal responsiveness to change. The regulatory mechanism should enable the system to respond quickly to changes in its environment.

(6) Insensitivity to perturbations in the structure of the system itself. Small changes in the system may be the result of mutations in structural or regulatory genes, errors in transcription or translation of the genetic information, or physical influences such as temperature shifts. These changes tend to exert a deleterious effect on the cell and, as Sonneborn suggested[33], cells "buffered" against such harmful effects are likely to have a selective advantage.

Repressor-controlled systems

Models of classical and autogenous regulation are represented schematically in Fig. 1. In the classical Jacob–Monod model the structural gene for the regulatory protein is located in a separate transcriptional unit and is itself unregulated, whereas in the model of autogenous regulation one of the protein products of the operon is the regulator, which therefore directly controls expression of its own structural gene. For purposes of comparison these models are assumed to be equivalent except for their differences in regulatory interaction.

These two models can be compared for a wide variety of conditions, and because there are several criteria to consider, a meaningful tabulation of all the results presents a problem. Figure 2, however, is a rather simple diagram that conveniently summarises many of these results. In this plot the vertical axis represents the strength of the contribution of end product to the regulation while the horizontal axis represents the strength of the autogenous contribution. Each point in this two-dimensional space represents a different system with distinctive properties. Nevertheless, this space can be divided into subclasses of systems that have similar properties.

In repressible systems that utilise a repressor mechanism, the end product has a negative effect on transcription, and the autogenous contribution is also negative. Since both contributions are negative, only the lower left hand quadrant of Fig. 2 needs to be considered. The vertical axis in this quadrant is the locus of points representing systems with constitutively synthesised repressor, since the autogenous contribution is zero Line *b* represents another important classification. The position of this line is determined by analysing the local stability of these models. All systems represented by points above line *b* are stable (if perturbed momentarily, they will return to their predisturbance condition), whereas all systems represented

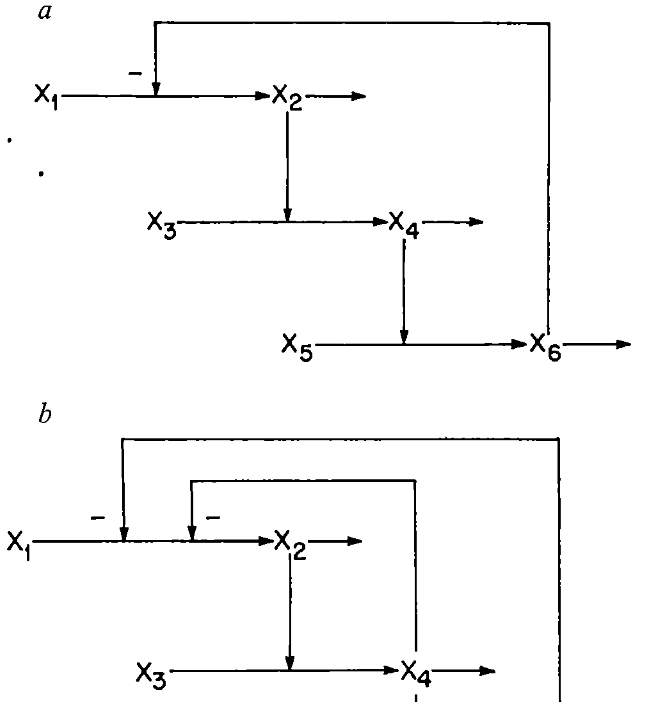

Fig. 1 Schematic models of repressible biosynthetic systems. Model with constitutive synthesis of the regulatory protein, which is not explicitly indicated. *b*, Model with autogenously regulated synthesis of the regulatory protein. X_1, Weighted sum of the nucleotide pools; X_2, specific messenger RNA; X_3, weighted sum of the amino acid pools; X_4, enzymes of the biosynthetic pathway (plus regulator in the case of autogenous regulation); X_5, substrate, and X_6, product/modifier. The horizontal arrows indicate chemical transformations at the mRNA, enzyme and metabolite levels. The vertical arrows represent modifier or catalytic influences (the sense of the influence is positive unless otherwise indicated). Except for the differences in regulation these models are assumed to be identical.

below this line are unstable (they will not return to their predisturbance condition).

Lines, such as *c*, *d* and *e*, that radiate from a single point on this plot are lines of equivalence with respect to the first three criteria for functional effectiveness. All systems whose regulatory parameters have values that determine points on a given line of equivalence have: (1) the same steady-state response to a change in demand for the end product, (2) the same steady-state response to a change in substrate availability and (3) the same decrease in enzyme synthesis for a given increase in the concentration of extracellular end product. The slope of the line determines the magnitude of the above three responses. Systems represented on a steeper line of equivalence, function more effectively according to the first and third criteria but less effectively according to the second

Systems for which the second criterion is of primary importance are represented by lines of equivalence with low slope, for example, line *c*. As previously noted, all systems on such a line have identical responses according to the first three criteria. Comparisons on the basis of stability, the fourth criterion, can be made by noting the relative distances of points on line *c* from the boundary of instability, line *b*, in Fig. 2. Since lines *c* and *b* diverge to the left, systems with greater strengths of autogenous regulation are represented further from the boundary of instability than is the equivalent system with constitutive synthesis of repressor. Consequently, this latter system is the least stable of all the systems represented on the line of equivalence *c*.

Systems for which the first three criteria are of equal importance are represented by lines of equivalence with intermediate slope, such as line *d* in Fig. 2 All the systems represented on this line have identical responses according to the first three criteria. They also have the same degree of stability since line *d* is parallel to the boundary of instability, line *b*.

Similarly, systems for which the first and third criteria are of primary importance are represented by lines of equivalence with steep slope, for example, line *e* in Fig 2 These systems are equivalent as judged by the first three criteria, but the systems with autogenously regulated synthesis of repressor must be considered inferior to the equivalent one with constitutive synthesis of repressor according to the fourth criterion because autogenous regulation now is clearly a destabilising influence

The two types of repressor-controlled systems are examined in Fig. 3 on the basis of temporal responsiveness, the fifth criterion for functional effectiveness. The three panels in this figure correspond to the three different classes of equivalence represented by lines *c*, *d* and *e* in Fig. 2. In the top panel (*c*) the response labelled 0.0 corresponds to the system with constitutive synthesis of repressor. The system is in a steady state with concentrations normalised to unity before time zero. At $t=0$ the concentration of extracellular end product is increased and then maintained at an elevated level throughout the experiment. The concentration of intracellular end product is plotted as a function of time. Similar responses are plotted for a series

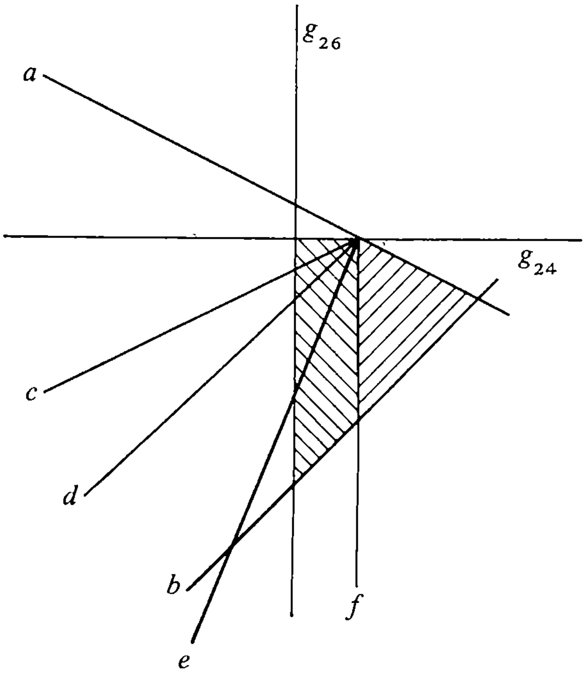

Fig. 2 Graphical comparison of systems with alternative types of regulation. The vertical axis represents the strength of the product's contribution to the regulation of transcription and the horizontal axis represents the strength of the autogenous contribution to this regulation *a* and *b*, Boundaries of instability. *c*–*f*, Lines of equivalence with respect to the first three criteria for functional effectiveness The vertical axis is the locus of points representing systems with constitutive synthesis of either activator or repressor. The shaded areas to the right of this axis are the locations of points representing stable systems with autogenously regulated synthesis of activator. Similarly, the area above line *b* in the lower left hand quadrant represents stable systems with autogenously regulated synthesis of repressor. (See text for further discussion)

of systems with different strengths of the autogenous contribution to the regulation. Clearly, autogenous regulation decreases the time required for the system to settle into the new steady state. The same is true in Fig. 3*d*. In Fig 3*e*, however, autogenous regulation actually increases the response time.

A comparison on the basis of the sixth and final criterion for functional effectiveness shows that the sensitivities to external perturbations of the systems with autogenously regulated synthesis of repressor are less than or equal to those of the system with constitutive synthesis of repressor.

On the basis of the comparisons discussed above one can draw the following conclusions. If the second criterion for functional effectiveness is of primary importance, then systems with autogenously regulated synthesis of repressor will have a selective advantage. The behaviour of these systems is superior to that of systems with constitutive synthesis of repressor on the basis of the second, fourth, fifth and sixth criteria, but inferior with regard to the first and third. But if the first and third criteria for functional effectiveness are of primary importance, as seems more reasonable for biosynthetic systems, then systems with constitutive synthesis of repressor will have the selective advantage. The behaviour of these systems is superior to that of systems with autogenously regulated synthesis of repressor on the basis of criteria one, three, four and five, but inferior with regard to two and six. These conclusions will be discussed in relation to available experimental evidence in a later section.

Activator-controlled systems

The models represented in Fig. 1 also can be used for the comparisons in this section. Systems with constitutive synthesis of an activator protein can be represented directly by the model in Fig. 1*a*, whereas systems with autogenously regulated synthesis of activator can be represented by the model in Fig. 1*b* provided the negative sign previously associated with the repressor is changed to a positive one, implying activation. Since the autogenous contribution to the regulation now is positive, only the lower right hand quadrant of Fig 2 need to be examined. The systems with constitutive synthesis of activator are represented along the vertical axis. As in the previous section, line *b* represents the lower boundary of stability. In addition, there is an upper boundary of stability given by line *a*. As in the previous section, lines, such as *c*, *d*, *e* and *f*, that pass through a common point on this plot are lines of equivalence with respect to the first three criteria for functional effectiveness.

Systems for which the second criterion is of primary importance again are represented by points on line *c*. These systems are equivalent with respect to the first three criteria, but since line *c* diverges to the left from the boundary of instability, line *b*, the system with constitutive synthesis of activator is more stable than the equivalent systems with autogenously regulated synthesis of activator Systems for which the first three criteria are of equal importance are represented by points on a line of equivalence with intermediate slope, such as line *d*. All the systems represented on this line have identical responses according to the first three criteria, and according to the fourth criterion as well, since lines *b* and *d* are parallel. Similarly, systems for which the first and third criteria are of primary importance are represented by a steeper line of equivalence, such as *e* in Fig. 2. These systems are also equivalent by the first three criteria, but those with autogenously regulated synthesis of activator must be considered superior to the equivalent one with constitutive synthesis of activator according to the fourth criterion because autogenous regulation is a stabilising influence. Thus, the effect of autogenous regulation on the stability of activator-controlled systems is just the opposite of that found to be true for repressor-controlled systems.

The results in Fig. 4 show that autogenous regulation also has opposite effects on the response times of repressor-controlled and activator-controlled systems. The three panels in this figure correspond to the three different classes of equivalence represented by lines *c*, *d* and *e* in Fig. 2 The response time is increased by autogenous regulation in Fig. 4*c* and *d* In Fig. 4*e*, however, the response time is decreased by autogenous regulation.

A comparison on the basis of system sensitivity, the sixth criterion, shows that the sensitivities to external perturbations of the system with constitutive synthesis of activator always are less than or equal to those of the equivalent systems with autogenously regulated synthesis of activator.

The following conclusions can be drawn from the comparisons in this section. If the second criterion for functional effectiveness is of primary importance, then systems with constitutive synthesis of activator will have a selective advantage. These systems are superior to systems with autogenously regulated synthesis of activator by the second, fourth, fifth and sixth criteria, but inferior according to the first and third. If, however, the first and third criteria for functional effectiveness are of primary importance, as seems more reasonable for biosynthetic systems, then systems with autogenously regulated synthesis of activator will have the selective advantage. These systems are

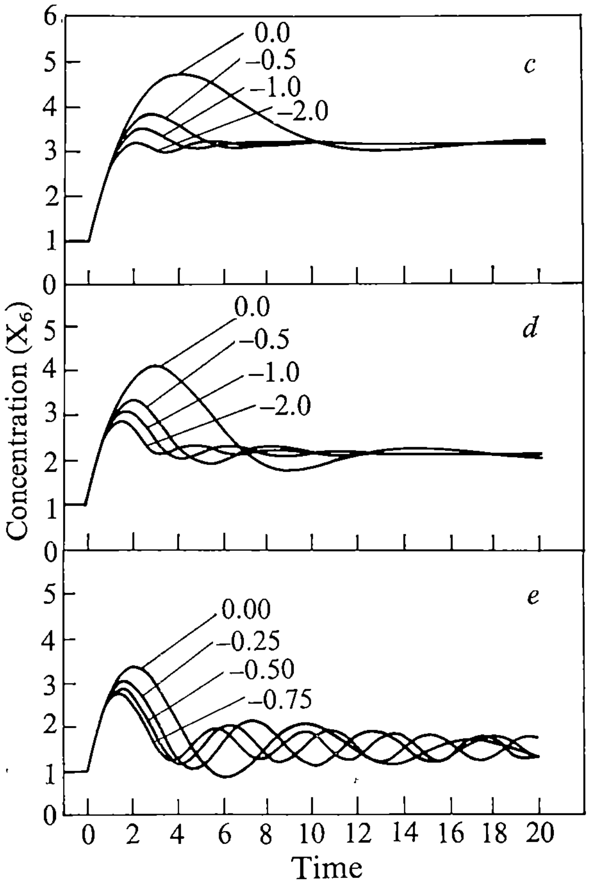

Fig. 3 Temporal responsiveness of systems with autogenously regulated synthesis of repressor. *c*, *d* and *e* correspond to systems in the three different equivalence classes represented by lines *c*, *d* and *e* in Fig 2. The numbers associated with the individual curves are values of g_{24}, representing the strength of the autogenous contribution to regulation. The corresponding values for the parameter g_{26} are chosen so that the points representing the different systems within a class all lie on the same line of equivalence. Curves with $g_{24} = 0$ represent systems with constitutive synthesis of repressor. (See text for further discussion.)

superior to systems with constitutive synthesis of activator on the basis of criteria one, three, four and five but inferior with regard to two and six.

(Re-examination of the lower right-hand quadrant in Fig. 2 shows that only a portion of the allowable systems have been considered in the preceding comparisons. The remaining systems with autogenously regulated synthesis of activator exhibit two classes of behaviour for which there is no counterpart among the other types of regulatory systems considered here Line *f* represents the class of systems for which there is zero depletion of end product in steady state after an increase in demand for end product. The class of systems represented by points within the shaded triangular region to the right in Fig. 2 have the unique property of responding to an increased demand for end product by increasing the level of that end product—a response to demand that is the inverse of the usual one. Whether such behaviour has biological significance is unclear and it will not be discussed further here A more detailed analysis is given in ref. 31.)

Predictions and observations

As previous sections of this article show, the effectiveness of activator-controlled and repressor-controlled operons is changed in opposite ways if the regulator protein is, in addition, autogenously regulated. In systems for which the first and third criteria for functional effectiveness are most important, as is likely for repressible biosynthetic systems, autogenous regulation of the regulator protein improves the performance of activator-controlled systems and degrades that of repressor-controlled systems. Thus, biosynthetic systems governed by a repressor are not expected to use autogenous regulation, while those governed by an activator can be predicted to involve such regulation. These predictions were deduced from differences inherent in the classical and autogenous modes of regulation, other things being equal. Present information concerning actual, specific operons is insufficient to yield such generalisations through induction from individual cases. Nevertheless, the experimental evidence is consistent with the above predictions in the few cases where data that can be analysed are available.

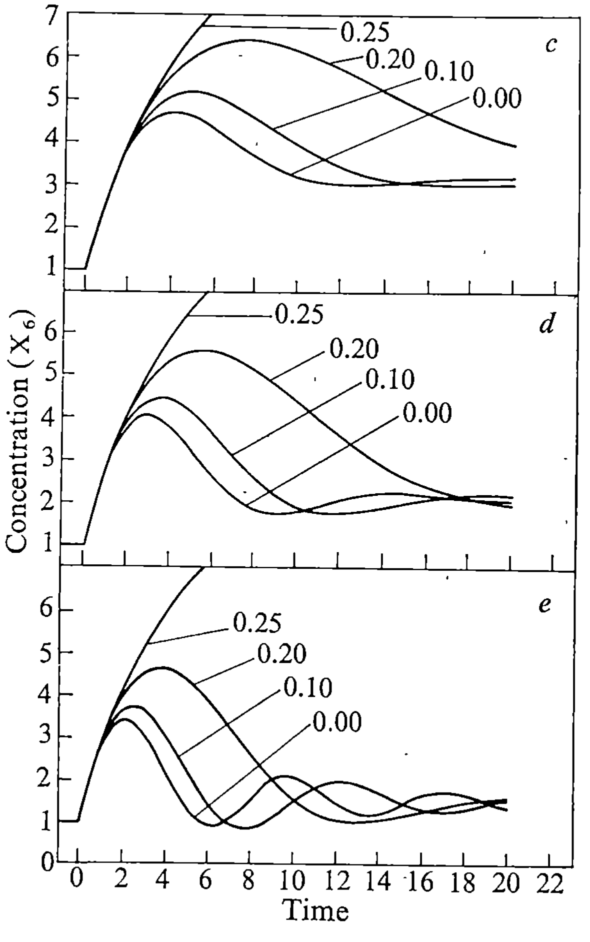

Fig. 4 Temporal responsiveness of systems with autogenously regulated synthesis of activator. *c*, *d* and *e* correspond to systems in the three different equivalence classes represented by lines *c*, *d* and *e* in Fig. 2 The numbers associated with the individual curves are values of g_{24}, representing the strength of the autogenous contribution to regulation. The corresponding values for the parameter g_{26} are chosen so that the points representing the different systems within a class all lie on the same line of equivalence. Curves with $g_{24} = 0$ represent systems with constitutive synthesis of activator. (See text for further discussion.)

In the case of the tryptophan operon in *E. coli*, the best documented example of a biosynthetic system involving control by a repressor, there is no evidence for autogenous regulation of repressor. The structural gene for the tryptophan repressor is located outside the known transcriptional units under its control[34], so the simplest form of autogenous regulation is excluded. Nevertheless, a more complex, regulon model, in which the repressor modulates expression of its own structural gene in parallel with that of the tryptophan operon, cannot be excluded rigorously since repressor levels have not been compared in strains with the tryptophan operon repressed and derepressed.

In the case of the arginine system in *E. coli*, which also seems to involve control by a repressor, there is no evidence for autogenous regulation of repressor. Although the arginine system itself constitutes a regulon with several unlinked transcriptional units regulated in parallel[35], the structural gene for the repressor is not linked to any of these[34] and there is no evidence that its expression is subject to modulation by the level of arginine within the cell.

On the other hand, the clearest example of a biosynthetic system involving control by an activator is the isoleucine–valine system in *Saccharomyces cerevisiae* and in this case the activator is autogenously regulated[36,37]. With an extensive collection of mutants in the structural gene for the first enzyme of the isoleucine pathway (threonine deaminase), Bollon[37] has constructed a fine-structure map and demonstrated that this protein is multifunctional; mutations affecting its activator function overlap with mutations affecting its catalytic function.

For all three operons discussed above the evidence is consistent with the predictions based on the analysis of autogenous regulation. For other biosynthetic systems the experimental evidence is more ambiguous. For example, in *E. coli* there is strong experimental evidence that the first enzyme of the isoleucine pathway is involved in the autogenous regulation of the isoleucine–valine system, but whether it functions as repressor or activator is unclear. The prediction based on the analysis in the preceding sections is that some product of the operon is an activator, in agreement with the data of Levinthal *et al.*[28]. Similarly, in *S. typhimurium* there is evidence consistent with the idea that some product of the histidine operon is involved in autogenous regulation of the system, but whether this product is an activator or a repressor is controversial. Again, the prediction is that this product is an activator, in agreement with the data of Artz and Broach[22]. (The conflicting evidence for the nature of the regulators of these operons, which was referred to in the introduction, might be reconciled more easily if they were in fact biregulators rather than activators It is easier to conceive of a biregulator changing physical state, as a result of mutation or environmental conditions, and exhibiting the properties of either repressor or activator than to imagine an activator doing this. Nothing in the analysis and predictions given above would change substantially if activators were considered biregulators analogous to the arabinose *C*-gene product, which is primarily an activator in function but also has repressor attributes. The arguments are given in ref. 31.)

The tryptophan and arginine biosynthetic systems have been described in terms of a classical, Jacob–Monod model with constitutive synthesis of regulator. On the other hand, the histidine and isoleucine–valine biosynthetic systems have been described in terms of an autogenously regulated model with an enzyme/regulator directly involved in modulating expression of its own structural gene. These two models, however, need not be mutually exclusive. A combination of the two modes of regulation might exist, possibly with one or the other mode playing a dominant role in some systems. The results in the preceding sections suggest that the most promising of such combinations would be constitutive synthesis of a repressor and autogenously regulated synthesis of an activator. Is there any experimental evidence for such a combination?

There is evidence for multiple control mechanisms in most of the biosynthetic systems that have been well studied. Mutants with a chain-termination codon early in the structural gene for the first enzyme or with this gene deleted have been described in the histidine[19] and isoleucine–valine[38] biosynthetic systems of enteric bacteria. In each case, the system continues to be regulated in an apparently normal manner, at least by the usual all-or-none tests for regulatory function. Thus, mutations that eliminate the autogenous mode of regulation permit another, possibly the classical mode, to become manifest.

A better example is provided by the tryptophan operon of *E. coli* In this system, where there is clear evidence for the classical mode of regulation involving a constitutively synthesised repressor, there also is evidence suggesting that the first enzyme of the tryptophan pathway (anthranilate synthetase, EC 4 1 3.27) is involved in regulating expression of the operon [39]. Somerville and Stetson[40,41] reported additional evidence for involvement of the first enzyme in regulation of the tryptophan operon and suggested that this enzyme is normally an activator or positive element in the control, which agrees with the above prediction. When the structural gene for the first enzyme is deleted, the tryptophan operon continues to be regulated in an apparently normal manner, again by the usual all-or-none tests for regulatory function[42]

In addition to the two modes of regulation discussed above there are indications of novel control mechanisms[43–45], at least some of which involve sites on the DNA between the promoter–operator region and the first structural gene of the operon[44,45].

In systems for which the first and third criteria for functional effectiveness are relatively unimportant, the results are just the reverse of those discussed above Autogenous regulation of the regulator protein improves the performance of repressor-controlled systems and degrades that of activator-controlled systems Although it seems unlikely that any repressible biosynthetic system would fall into this particular class, there are systems of other types that might be considered non-biosynthetic, that do fit this category. For example, Sompayrac and Maaløe[46] have proposed a model for regulating the concentration of the protein(s) believed to be involved in the initiation of DNA replication The regulator protein in this model is autogenously regulated and functionally autonomous, that is, it does not require the participation of an effector molecule in its regulatory function. Although not a repressible biosynthetic system in the conventional sense of the term, formally this model is a special case of that represented in Fig. 1*b* with $g_{26} = 0$. Accordingly, such systems would be represented along the horizontal axis in Fig. 2 Sompayrac and Maaløe[46] pointed out several advantages for their model involving a repressor whose synthesis is autogenously regulated. The results in the preceding sections suggest that the behaviour of such systems is optimal with respect to stability, temporal responsiveness and insensitivity to perturbations in the structure of the system itself. Dennis and Nomura[47] have indicated that in *E. coli* a similar mechanism of autogenous regulation might be involved in control of ribosomal protein genes.

Perhaps it should be re-emphasised here that the predictions made throughout this article are based on a particular weighting of the different criteria for functional effectiveness. If this choice were incorrect, then the predictions could be wrong, but clearly for reasons that have nothing to do with the general validity of the approach used.

In conclusion, the expression of biosynthetic operons in enteric bacteria is undoubtedly controlled by several different mechanisms acting in concert This has made it difficult to study regulation *in vivo* where all the elements may interact or contribute in various degrees to produce the end result. The identity of the elements participating in the regulation and the nature of their roles at the molecular level can only be established rigorously *in vitro*. An understanding of the intact regulatory system, however, will require knowledge of the functional implications at the physiological level for each molecular mechanism and, eventually, integration of the individual mechanisms into an accurate model of the intact system With progress being made in each of these areas, the understanding of repressible biosynthetic operons should soon be as thorough as it is of the simpler inducible catabolic operons.

I thank Robert F. Goldberger and Stanley W. Artz for valuable suggestions during preparation of the manuscript This research was supported in part by grants from the National Science Foundation and an institutional research grant to the University of Michigan from the American Cancer Society.

letters to nature

Soft X-ray search of centre of Cygnus Loop

THE Mullard Space Science Laboratory equipment on the Copernicus satellite has been used to search, with negative results, for evidence of a compact object in the centre of the Cygnus Loop supernova remnant.

Rocket measurements[1] indicate that a central object exists, and contributed, at the time of observation, about 4% of the X-ray flux from the entire loop. This object may be variable[1,2] in intensity, and may even be pulsing[1]. Reanalysis of earlier rocket data[3] gives statistically more significant evidence for pulsation, but at a different frequency, which would be consistent with a compact object which is not a pulsar. The same data require, however, that the pulsing object be roughly equal in brightness to the integrated brightness of the rest of the nebula at the relevant energy, 0.28 keV, at the time of observation, while other rocket data[4,5] show that this is certainly not the case at particular other times. The availability of a Channel Electron Multiplier (CEM) detector, sensitive at the relevant energy (0.28 keV), on board the Copernicus satellite, has provided the opportunity to observe the centre portion of the Cygnus Loop and to test whether a central object does, from time to time, radiate as strongly at 0.28 keV as rocket data[3] suggest.

The CEM has been described by Margon *et al.* (see ref. 6 and references therein). The field-of-view of the CEM is 15′ full width at half maximum. Since the exact position of the central object is not known, a set of nine observing sections, centred on the rocket[1] position, were chosen so that there was a slight degree of overlap. These nine positions are given in Table 1.

The observations were made on May 19, 1974. Three spacecraft orbits were required to observe the nine sections. Sections, 1, 2, 3 were covered from 1349 to 1422 UT; 6, 5, 4 from 1530 to 1600 UT; and 7, 8, 9 from 1709 to 1739UT. The observations could only be made while the satellite was in the shadow of the Earth since the CEM is also sensitive to Lyman alpha (Lα) radiation. During the periods when the satellite was in sunlight, the CEM was turned off. (Margon *et al.*[6] note that in spite of the Lα background, the telescope is known to respond normally to low energy X rays; in particular Sco X-1 has been observed.) Each data acquisition interval lasted 62.5 s. From six to ten observations were made in each section.

Figure 1*a* presents plots of the raw data as received from the satellite. Three points are immediately apparent: (1) each plot displays a characteristic parabolic shape, due to CEM sensitivity to geocoronal Lα radiation; (2) a systematic decrease in this background occurs on successive orbits, clearly due to instrumental effects; and (3) no sharp break occurs between any of the three sections on each of the three orbits, as would be expected if a strong source of 0.28 keV X rays were present. If the central source were present, at the greatest intensity observed[3], we would expect that one of the sections would display a 'discontinuity' of about 735 counts over the Lα background, given the known sensitivity[6] to X rays of the CEM. A lower flux would result in a smaller discontinuity. The data show that if such a source was present in the field of view, it was not of high intensity at the time of observation.

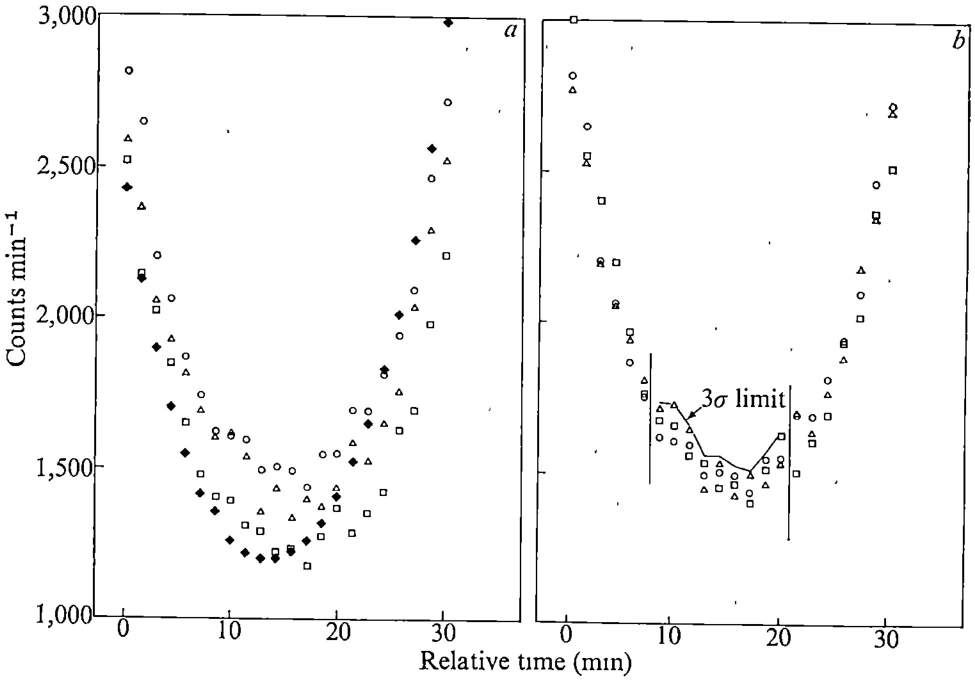

Fig. 1 *a*, Signal received from directions near the centre of the Cygnus Loop nebula on three orbits of the Copernicus satellite. The data are shown in raw form, and give no evidence for any soft X-ray emission. Also shown is the relative expected background of Lα radiation, calculated by Dr R. Meier of the US Naval Research Laboratory. *b*, The data of *a* are shown, processed to remove instrumental effects. This permits the determination of a 3σ upper limit on any possible X-ray source, which is about 80 times smaller than the highest reported observed intensity. ○, First orbit; △, second orbit; □, third orbit; ◆, theoretical Lα.

The change in sensitivity of the CEM would be unimportant if an obvious discontinuity in the data was apparent. One could say in those circumstances that a source was present, and one could determine in which section it appeared. In obtaining an upper limit for the source, however, the change in sensitivity becomes critical. Since each orbit displays the same characteristic pattern, we feel safe in believing that each curve represents only Lα background. We have therefore transformed orbit two and orbit three to orbit one by using a simple *ad hoc* function that corrects for the CEM drift. Almost any transformation will be acceptable if it results in a variance at each point comparable to some typical variance of the data points on one orbit about some smooth function representing the Lα background.

Figure 1*b* represents the result of using a correction consisting simply of multiplication of the data by an orbit-dependent constant. The constant for each orbit was chosen so that

$$\sigma^2 = \sum_{i=1}^{N} \sigma_j{}^2 = \sum_{j=1}^{N} \sum_{i=1}^{3} \left\{ \frac{(x_{ij} - \bar{x}_j)^2}{2} \right\} \qquad (1)$$

was a minimum where $\bar{x}_j$ is the average of the three transformed points, x_{ij} is the transformed value of point j in orbit i, and N observations are made during one orbit.

Table 1 Observed positions in the Cygnus Loop

Section	Position (1950) RA (h min)	Dec. (° ′)
1	20 50.5	+30 53
2	20 49.7	30 53
3	20 48.9	30 53
4	20 50.5	30 43
5	20 49.7	30 43
6	20 48.9	30 43
7	20 50.5	30 33
8	20 49.7	30 33
9	20 48.9	30 33

The minimum σ^2 was obtained by multiplying the observations of orbit 2 by 1.07 and of orbit 3 by 1.19, and each $\sigma_j{}^2$ was indeed comparable to the scatter among individual points observed on a single orbit, indicating that no more complicated correction procedure is justified.

A three sigma upper limit on the intensity of any soft X-ray source may be obtained by adding a source of ε photons per 62.5 s to the background Lα radiation in one of the sections in Fig. 1*b*. The value of ε is increased until the quantity

$$\chi^2 = \sum_{j=1}^{n} \frac{((\bar{x}_j + \varepsilon) - \bar{x}_j)^2}{\sigma^2{}_j} \qquad (2)$$

(where n is the number of observations in a section), becomes so large that one can say with 99.74% certainty that the data in that section include something more than Lα radiation. The line in Fig. 1*b* represents this three sigma limit.

Knowing the relevant parameters of the CEM, a three sigma upper limit on the intensity of the X-ray source of 5.7 photons (cm^2 s keV)$^{-1}$ is obtained. This is a factor 80 below the highest reported rocket intensity[3].

This negative result could indicate that the X-ray source was simply not in its high-intensity mode at the time of observation, or could arise because the source is at some other location in the Loop. The possibility also remains, of course, that the evidence for a central object[1], intensity variations[1,2], and pulsations with very high intensity[3], is misleading and no such object exists If it does exist, it is clear that it is strongly time-dependent, and it would be valuable to monitor the assumed source position frequently. Unfortunately noise bursts on the CEM channel have precluded additional observations.

We thank Dr R. Meier and Professor R. L. F. Boyd for help. This research was supported by NASA.

Proper motions of six pulsars

SEVERAL authors have suggested that pulsars may be high velocity objects. Prentice[1] found, from a study of the wide distribution of the distances of pulsars to the galactic plane, that their initial velocities may have been as high as 100 km s^{-1}, and Michel[2] obtained a similar figure for runaway objects formed by the collapse of core fragments in supernova events. Tademaru and Harrison[3] proposed a mechanism for the acceleration of pulsars, by asymmetric radiation, to velocities of 1,000 km s^{-1} Only rather meagre direct experimental evidence for high velocities exists, however. This evidence is derived from three different types of observation. First, Lang and Rickett[4], Galt and Lyne[5], and Slee *et al*[6] have deduced velocities of between ~ 40 km s^{-1} and ~ 600 km s^{-1} from measurements of the velocity of the interstellar scintillation pattern, found by comparing the scintillation observed at two widely separated stations. These conclusions rely, however, on the pattern being stable in time. In some cases this is clearly not so, and in particular Uscinsci[7] has shown how shear within the scintillating medium can produce an apparent velocity which bears little relation to that of the pulsar. These measurements must therefore be treated with caution Second, pulse-timing studies by Manchester, Taylor and Van[8] gave an apparent motion of 0 58±0.22″ for PSR1133+16, corresponding to a velocity of 380 km s^{-1}. Finally, the transverse velocity of the optical object identified with the Crab Nebula pulsar, PSR0531+21, is 100 km s^{-1} as deduced from the proper motion and estimated distance[9].

Here we report measurements on six pulsars which seem to have motion velocities at least five times greater than the formal standard errors Measurements were made on a radio link interferometer of 127-km baseline, using the Mk 1A 76-m radio telescope at Jodrell Bank and a 25-m

* $\pm2\sigma$

antenna at Defford, Worcestershire, used by arrangement with the Royal Radar Establishment, Malvern. The observing frequency was 408 MHz, with an operating bandwidth of 4 MHz. A phase reference technique similar to that described by Peckham[10] was used, in which the pulsar and a small diameter background radio source are observed simultaneously within the same telescope beam. The relative phases of the two objects are compared at different epochs and, assuming that the background source is extragalactic, any change in the relative phase is then attributed to a proper motion of the pulsar.

Observations were made in November 1973, July 1974, November 1974 and April 1975. Seven pulsars were observed in 1973, and these and a further seven in the subsequent sessions. At each epoch, each pulsar was observed for as wide a range of hour angles as possible when its elevation was greater than 10°. If time permitted, each observation was repeated.

Table 1 shows the proper motions tabulated in both celestial coordinates and polar coordinates. The velocities given in the final column were calculated using the distances presented in the penultimate column. These distances were obtained from the dispersion measures, assuming an average electron density of 0.03 cm^{-3} (refs 11 and 12), except in the case of PSR0329+54, for which absorption measurements place the pulsar on the near side of the Perseus arm of the galaxy (R. S. Booth and A. G. Lyne, unpublished). This use of the dispersion measure is somewhat uncertain, but we believe that it is justified since Prentice and ter Haar[13] found no regions of high ionisation along the line of sight to any of these pulsars. We have not used their distance estimates directly, because of the rather high mean electron density (0.05 cm^{-3}) used in their model. The discrepancies are not large, however.

The uncertainties quoted in Table 1 are all formal 2σ errors, and these are a function of the intensity of the source and the pulsar, and also of the observing time and hour angle coverage. These errors should be treated with caution, since ionospheric and interstellar scintillation effects can cause fluctuations in the relative-phase curves on time scales comparable with the length of an individual observation. Although the effects of these scintillations will average out as a larger number of observations are made, with the data obtained so far we do not believe the uncertainties can be much less than 0.01″ yr^{-1}. In the case of PSR0329+54, however, the measurements are expected to have less uncertainty, because it is a relatively intense pulsar with a strong background source, it was observed at high elevations, and several repeat observations were made.

The results for the two pulsars PSR0329+54 and PSR1133+16 show some agreement with previous measurements. In the case of PSR0329+54, the measured position angle of 126±16° agrees well with the value of 115±15° found by Galt and Lyne[5] from scintillation observations. This supports their second interpretation: that it is the pulsar, rather than the diffraction pattern, which is moving with high velocity They deduce a velocity which is more than a factor of two greater than the present measurement, but this could be explained if the diffracting screen were situated slightly nearer the pulsar, or if the distance has been underestimated. Our result for PSR1133+16 agrees, within the errors in both magnitude and direction, with that of Manchester, Taylor and Van[8].

The data in Table 1, together with that for the Crab Pulsar, PSR0531+21, show typical transverse velocity components in the range 100–200 km s^{-1}. Thus we may deduce that the resultant velocities are high, typically 150–300 km s^{-1}, although none is as high as the 1,000 km s^{-1} suggested by several authors[1–3]. It must be remembered, however, that we are, as yet, dealing with very small numbers of pulsars, and also that there are still some uncertainties in these velocities because of the uncertainties in the pulsar distances.

It is widely believed that pulsars originate in population I type objects which lie within about 100 pc of the galactic plane, and that their high velocities then carry them to heights of several hundred parsecs during their lifetimes. This picture is weakly supported by the data presented in column 8 of Table 1 which shows the angle ($-90° < \varphi < 90°$) between the velocity vector $\dot{\mathbf{r}}$ and the galactic plane. A positive sign indicates that the apparent motion is away from the galactic plane. It can be seen that three of the pulsars (PSR0823+26, PSR0834+06 and PSR1133+16) are probably moving away from the plane; the direction of motion of PSR0329+54 is not established accurately enough to ascertain whether it is receding from or approaching the plane; and PSR2016+28 and PSR1237+25 seem to be approaching the plane. PSR0329+54 and PSR2016+28 lie within the population I distribution, however, and PSR1237+25 is situtated at such a high galactic latitude (86.5°) that motion towards or away from the plane is likely to be dominated by the unknown radial component of velocity. The unknown radial components of velocity of the other pulsars also affect their apparent motions with respect to the galactic plane so that the evidence for recession from the plane is not very strong.

Manchester, Taylor and Van[8] have estimated a 'kinetic age' for PSR1133+16 by projecting back the apparent motion on the assumption that it started from the galactic plane and that it now has no radial component of velocity. The pulsar velocity should be substantially unaffected by the gravitational attraction of the galactic plane during the pulsar lifetime since the oscillation period of a star across the plane is in excess of 10^8 yr in the region of the Sun. Table 2 shows the 'kinetic ages' for the three pulsars which clearly seem to recede from the galactic plane together with the 'rotational age' derived from observations of changes in

Table 2 Kinetic and rotational ages of three pulsars

Pulsar	Kinetic age ($\text{yr}\times10^{-6}$)	Rotational age ($\text{yr}\times10^{-6}$)
0823+26	11	5
0834+06	14	3
1133+16	3.4	5

pulsar periods ($P/2\dot{P}$). The 'kinetic ages' should be regarded as probable upper limits to the true ages of the pulsars since the ages would be significantly reduced if the pulsars had radial components of velocity as small as $+60 \text{ km s}^{-1}$. Because of this, these 'kinetic ages' are not sufficiently accurate to test a recent suggestion by Lyne, Ritchings and Smith[14] that the 'rotational age' may be a substantial overestimate of the true age, particularly in the case of old pulsars.

It is worth noting that the proper motions which have been determined, so far, for pulsars—the six reported here and also the Crab Nebula pulsar, PSR0531+21 (ref. 9)—tend to lie parallel to the galactic plane rather than perpendicular to the plane. The probability of this occurring by chance is quite small, although so few measurements are available that the significance is difficult to assess.

Continuation of this work over longer time scales will yield improvements in accuracy, and provide measurements of a larger number of proper motions. These will be particularly useful in discriminating between genuine and false pulsar–supernova associations and can provide independent measurements of pulsar ages.

We acknowledge the help of Dr H. P. Palmer and all other members of the Long Baseline Interferometry group at Jodrell Bank who have assisted with making the observations.

Energy spectrum of ultra high energy cosmic rays

AT energies above ~ 10^{17} eV it becomes increasingly difficult to maintain the observed near isotropy of ultra high energy cosmic rays if they are of Galactic origin, unless there is an extensive halo magnetic field, and the primaries are heavy nuclei[1]; instead, extragalactic origin is often assumed. The models proposed can be divided into three main groups: (1) 'universal', in which there is a class of galaxies in the Universe (of which our own is not a member) which are roughly uniformly distributed, and which generate the ultra high energy particles; (2) 'universal plus supercluster enhancement'[2], in which the existence of a supercluster is assumed—the enhanced density of galaxies in the SC allows a larger fraction, than is its share by volume, to have come from this region; and (3) 'Supercluster trapping'[3], where energetic phenomena in the SC generate the particles which are then trapped for periods of perhaps 10^9–10^{10} yr.

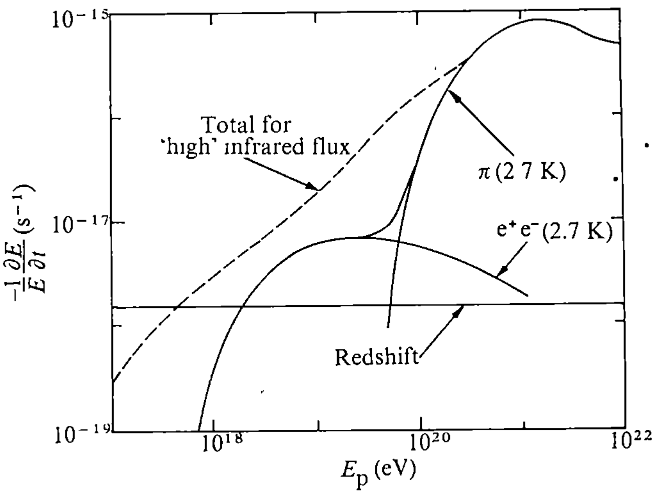

Fig. 1 Fractional rate of energy loss of protons. The solid lines represent the losses from π and e^+e^--production on the 2.7 K radiation field[2]. The dashed line is the aggregate rate of energy loss for the radiation field described in the text.

The problem with the universal model is that the universal black body radiation (2.7 K) should cause a rapid cutoff in primary intensity above about 6×10^{19} eV because of photomeson production[4,5], whereas the measured primary spectrum extends to 10^{20} eV (refs 6, 7 and papers in ref. 8), and perhaps to 3×10^{20} eV, without any indication of steepening. A similar situation exists in the 'supercluster trapping' model if the lifetime approaches the Hubble time.

We postulated the 'supercluster enhancement' model[2] in an effort to circumvent the difficulty by deriving quite a large fraction of the highest energy particle from nearby sources. There are difficulties in such a model, however, as we pointed out, because of the need to assume near-straight line trajectories; furthermore, there are questions about our membership of a supercluster (B. T. Jones, unpublished; J. N. Bahcall and P. C. Joss, unpublished).

The possibility of the extragalactic particles commencing their lives as heavy nuclei has been examined[9–12]. The conclusion is that heavy nuclei are not very helpful, but an important feature that has arisen from the examination of the propagation of heavy nuclei concerns the magnitude of the infrared component in extragalactic space. Puget and Stecker[12] derived so-called high and low infrared spectra. The 'high' infrared spectrum is quoted as $n(\varepsilon) = 1.1\times10^{-3}\ \varepsilon^{-2.6}$ (cm^{-3} eV^{-1}) valid for $2\times10^{-3}\text{ eV} < \varepsilon < 0.8\text{ eV}$ (giving a total energy density of $\sim 5\times10^{-2}$ eV cm^{-3}). There is no question of this being a definitive spectrum, in view of the paucity of observational data, but at least it is a possibility.

Our contribution now is to revert to the earlier situation[2] where extragalactic protons were considered. Figure 1 shows the fractional rate of energy loss for the case where only the 2.7 K radiation is considered and its modification when the 'high' infrared spectrum is included. It is now seen that the rapid rise in $(-1/E)\,(\partial E/\partial t)$ at $\sim 6\times10^{19}$ eV disappears, and instead there is a rather smooth variation over the whole range 5×10^{17}–10^{21} eV. The slope of the fractional rate of energy loss as a function of primary energy is almost unity, and this means that, for the universal model, if extragalactic sources have a production spectrum of the form E^{-2} then, above $\sim 5\times10^{17}$ eV, the spectrum at the earth will be close to that measured. (In this model the majority of particles below $\sim 5\times10^{17}$ eV are of galactic origin.) The assumption that extragalactic sources may have flatter spectra than that pertaining to our own Galaxy (for which the differential exponent is probably ~ 2.6: the measured exponent below ~ 10^{15} eV), is not unreasonable since these sources are more energetic.

For the supercluster enhancement model, there would again be agreement between observation and expectation; in fact there would be a flattening of the spectrum above about 10^{19} eV, where the SC contribution would start to dominate. It is pertinent to point out that there is indeed some evidence favouring such a flattening[13], a result that is also, incidentally, reasonable for a universal model in which sources having a variety of exponents contribute. Finally, the supercluster trapping model would give a very similar result to that for the universal model, if the particle lifetime is ~ 10^{10} yr. For a shorter lifetime the agreement would be reduced because the modulation caused by passage through the radiation fields would be smaller, although the infrared flux density within a supercluster will be higher than the universal average and some measure of compensation might be expected.

If the arguments advanced against the Galaxy belonging to the supercluster are correct and there is, in consequence, neither enhancement nor trapping, then the present suggestion seems to us to be one of the few ways of keeping a model with extragalactic protons. If later measurements show that the adopted infrared intensities are overestimates, then it is more likely that the ultra high energy particles are heavy nuclei of galactic origin and that there is an extensive halo.

The authors are grateful to F. W. Stecker, J. L. Puget, A. W. Strong, P. Kiraly, R. S. Ellis, A. A. Watson and J. L. Osborne for discussions.

Solar flare effects in equatorial counter electrojet currents

THE solar flare effect on the horizontal component of the geomagnetic field (H) during the period of counter equatorial electrojet current is characterised by a negative crochet (decrease of the H field) at an equatorial electrojet station and a positive crochet (increase of H field) at a low latitude station outside the electrojet belt. During the period of partial counter electrojet, the crochet in H may be positive at all low latitude stations but the amplitude decreases at stations nearer to the equator. We explain this as the combined effect of the solar flare on the normal eastward currents over the Equator associated with Sq current system (around 107–110 km) as well as on the westward counter electrojet current (~100 km) both flowing simultaneously over the low latitude stations, while at stations outside the equatorial region the solar flare effect is due to only the eastward Sq currents. (The Sq currents are currents in the upper atmosphere arising from convective motion through the geomagnetic field[1,2].)

McNish[3] has shown that disturbances in the geomagnetic field during a solar flare (crochet effect) were similar in direction and magnitude to the normal Sq vectors, suggesting that the crochets arise because of the intensification of the Sq current from additional ionisation by the radiations from the solar eruptions. Subsequent analyses, however, showed systematic differences between the current patterns of the crochet and the Sq field[4]. These differences led to the idea that normal Sq currents are restricted mainly to the E-region, but during the period of solar flare the ionospheric currents extend down to the D-region of the ionosphere.

Nagata[5] showed that the magnitude of the crochet in the H field is abnormally large at Huancayo and at other low-latitude stations. Forbush and Casaverde[6] showed that the amplitude of crochets in H at Peruvian stations varied with latitude in a manner similar to the Sq(H) range. At times the electrojet currents over a low-latitude station during the daytime are found to be reversed, that is, the currents flow westward causing a depression in the H field. These events called counter-electrojet are closely associated with the various phenomena on the lower as well as the upper ionosphere[7]. Rastogi[8] postulated the simultaneous existence of Sq currents at altitudes of ~107 km over the equatorial zone always flowing eastward and other currents at ~100 km flowing either westward or eastward. The net change in the geomagnetic H field at ground level is produced by the effects of both the current systems. If the solar flare somehow increases the

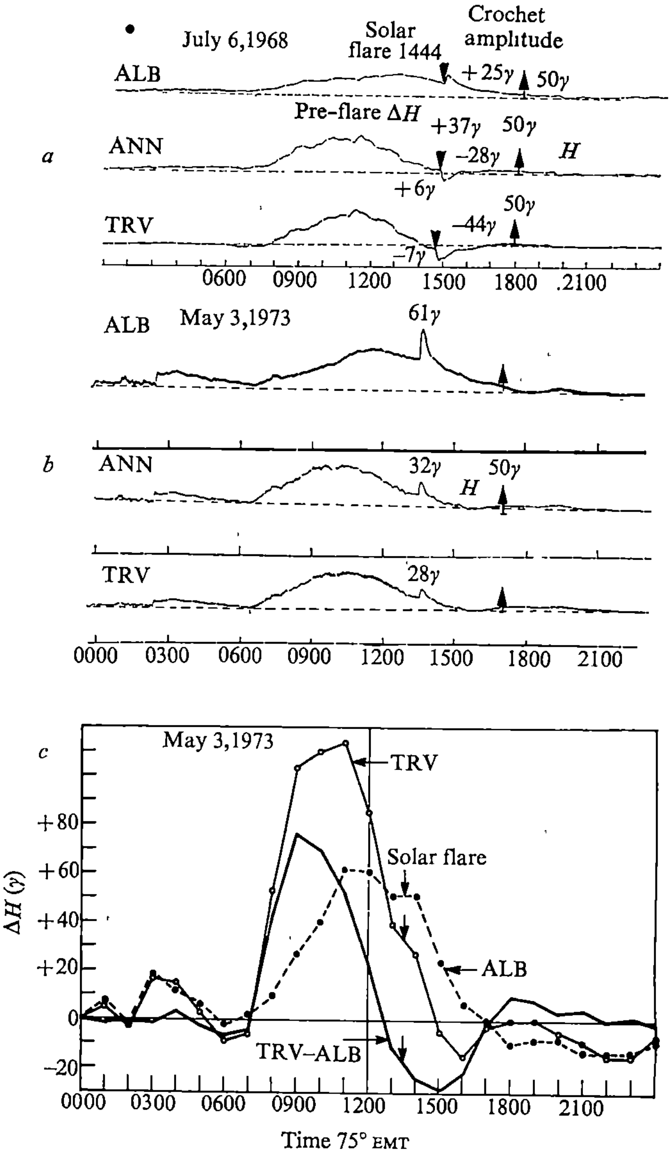

Fig. 1 *a*, Crochet effect in H at Indian stations during a complete counter-electrojet event on July 6, 1968 at Trivandrum (TRV), Annamalainagar (ANN), and Alibag (ALB). *b*, Crochet effect in H at Indian stations during a partial counter-electrojet event on May 3, 1973. *c*, Diurnal variations of the geomagnetic H field at TRV, ALB and TRV—ALB on May 3, 1973.

existing currents in the ionosphere, the effects of solar flares during periods of counter equatorial electrojets should be interesting. Here we examine magnetograms from Trivandrum (dip 0.6° S), Annamalainagar (dip 6°N) and Alibag (dip 25°N) for 1958–1973.

Figure 1*a* and *b* show magnetograms from these observatories during solar flares on July 6, 1968 at 1444 LT, when there was a clear counter electrojet, and on May 3, 1973 at 1330 LT, when there was a partial counter electrojet. Figure 1*c* shows the variations of the *H* field at Trivandrum, Alibag and the difference of the field between the two stations.

On July 6, 1968 the field at Trivandrum was below the night level when the flare occurred. The pre-flare ΔH was -7γ at Trivandrum, $+6\gamma$ at Annamalainagar and $+37\gamma$ at Alibag. The solar flare produced a change of -44γ at Trivandrum, -28γ at Annamalainagar and $+25\gamma$ at Alibag. Thus the crochet in *H* had opposite signs at stations within the electrojet belt and outside it, if the flare there was a counter electrojet.

For the solar flare on May 3, 1973, Srivastava[9] noted that the magnitude of crochet in *H* was larger at Hyderabad (dip 21°N) than at the equatorial stations. The magnitude of ΔH due to the solar flare was 28γ at Trivandrum, 32γ at Annamalainagar and 61γ at Alibag. Thus the crochet amplitude in *H* increased with increasing distance from the Equator, as opposed to the nature of the latitudinal variation Equatorial stations[10].

Figure 1*c* shows that after sunrise, *H* increased faster at Trivandrum than at Alibag until about noon. After 1230 LT, ΔH was smaller at Trivandrum than at Alibag. The ΔH(TRV−ALB) was negative from about 1230 to 1700. It has been shown that when ΔH at an equatorial station is positive, but the difference between this and ΔH at a station outside the electrojet region is negative, then the reversal of ionospheric drifts as well as the disappearance of plasma irregularities at the base of the ionospheric E region indicate a westward electric field, and so a counter-electrojet current is inferred[8]. Here, the *q* type of sporadic *E* at Kodaikanal had disappeared on the ionogram at 1245 LT precisely when ΔH (TRV−ALB) had reduced to zero and about half an hour before the occurrence of the flare. These facts clearly indicate the existence of the westward currents at the base of the *E*-region at the time of the occurrence of crochet on May 3, 1973.

At the stations outside the equatorial electrojet currents, Hyderabad and Alibag, where only the normal Sq currents exist, the crochet in *H* was due to the increase in the Sq currents only. At the equatorial stations, Trivandrum, Kodaikanal and Annamalainagar, the crochet in *H* was due to the combined effects of the intensifications of the normal Sq currents as well as of the counter-electrojet currents at a slightly lower altitude. Thus the magnitude of crochet in *H* on May 3, 1973 increased with distance of the stations from the Equator.

We thank Prof. K. R. Ramanathan and Shri B N. Bhargava for critical discussions and Dr H. Sastri for supplying the copies of the ionograms at Kodaikanal.

Accretional capture of the Moon

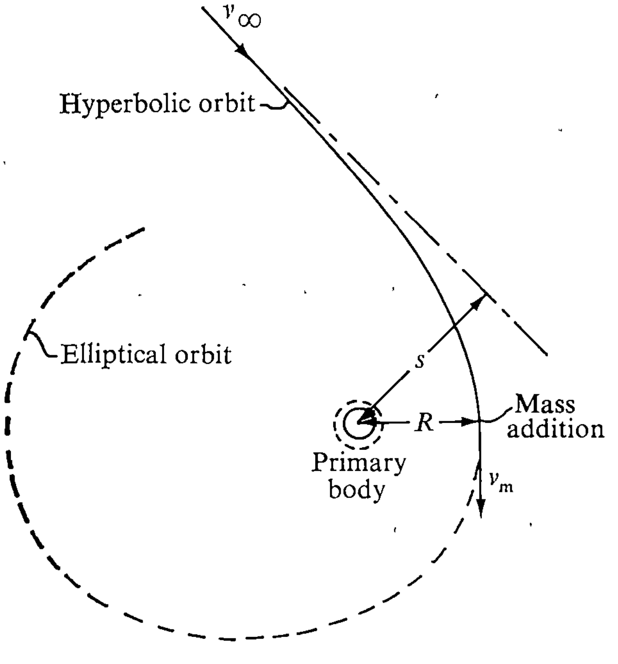
HYPOTHESES for the formation of the Earth–Moon system fall into one of three categories. The Moon was either (1) formed by fission from the Earth, (2) formed by accretion in Earth orbit, or (3) formed in solar orbit and then captured. We suggest that hypotheses (2) and (3) may be combined, with the result that many of the constraints on lunar origin are satisfied.

The primary difficulty with the hypothesis of lunar capture is its inherent improbability. Either collision or escape is much more likely, but capture could take place if sufficient dissipation occurred during a close approach of the Earth and Moon. It is unlikely, however, that tidal dissipation would be sufficient; an alternative would be collisional interactions with material already in Earth orbit[1]. Capture could also occur because of a change of mass of the Earth or Moon during a close approach[2]. It is this mechanism which we will discuss here. The closely related problem of orbital behaviour during mass loss from a binary star system has been considered by a number of authors[3–5].

Many calculations of planetary accretion have been carried out using particle mechanics. These calculations show that when an accreting body reaches a critical size, the gravitational attraction of the body greatly increases the rate of accretion. Opik[6] showed that if the Earth and Moon were accreted from common source material, and if the Earth was only slightly larger than the Moon during the early stages of accretion, the preferential gravitational accretion of the larger body could lead to the present mass difference. One consequence of this hypothesis is that the Moon should be enriched in early condensates; this is in fact the case[7,8]. We propose that capture took place during the final stages of the accretional process.

To estimate the effectiveness of accretional capture, we consider the following simple model: a small secondary body of mass *m*, in a hyperbolic orbit, approaches a large primary body of mass *M*. When the separation is a minimum, the mass of the primary body is increased to $M+\Delta M$. We derive the conditions under which this change in mass will result in an elliptic orbit (capture). The process is illustrated in Fig. 1.

Fig. 1 Illustration of accretional capture: the transfer from an initial hyperbolic orbit to an elliptical orbit due to mass addition of mass to the primary body at the point of closest approach.



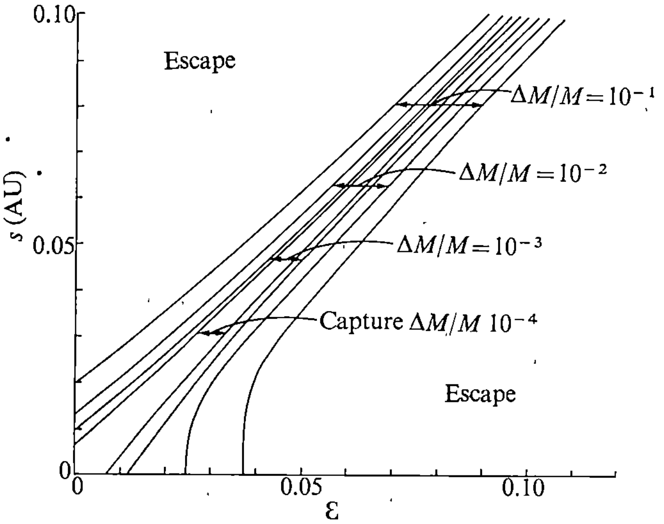


Fig. 2 Capture window for accretional capture: required values for the minimum separation s and eccentricity ε of the lunar orbit for various fractional increases in the Earth mass at the point of closest approach.

The minimum radial separation R, and the corresponding maximum relative velocity v_m are related to the approach velocity v_∞ and the impact parameter s by

$$\frac{s}{R} = \frac{v_m}{v_\infty} = \frac{GM}{s{v_\infty}^2} + \left(1 + \frac{G^2M^2}{s^2{v_\infty}^4}\right)^{1/2} \tag{1}$$

The sudden increase in the mass of the primary body is a non-conservative process, since there is a discontinuous change in the potential energy of the system. The secondary body suddenly finds itself in a stronger gravitational field, and may not have enough potential energy to escape.

After the change of mass, the total energy of the system is

$$E = \tfrac{1}{2}m{v_m}^2 - \frac{m(M+\Delta M)G}{R} \tag{2}$$

Capture occurs when $E<0$; the threshold value for capture is $E = 0$. Combining (1) and (2) with the condition $E = 0$ gives the mass increase required for capture

$$\Delta M = \frac{M}{2}\left[\left(1+\frac{s^2{v_\infty}^4}{M^2G^2}\right)^{1/2} - 1\right] \tag{3}$$

In order to relate the impact parameter s to the approach velocity v_∞, we assume that the two bodies are in independent orbits about the Sun. The primary body (the Earth) is assumed to be in a circular orbit with a radius r_e of 1 AU; the secondary body (the Moon) is assumed to be in an elliptic orbit with an eccentricity ε. The impact parameter s is taken to be the minimum radial separation between the bodies, and v_∞ the corresponding difference in orbital velocities; assuming $s/r_e \ll 1$ and $\varepsilon \sim 1$ these are related by

$$v_\infty = \pm\tfrac{1}{2}\left(\frac{GM_\odot}{r_e}\right)^{1/2}\left(\frac{s}{r_e} - \varepsilon\right) \tag{4}$$

Note that if $\varepsilon \approx s/r_e$, the approach velocity is small and the probability of capture is enhanced.

Combining equations (3) and (4) gives

$$\frac{s}{r_e} - \varepsilon = \left(64\frac{M\Delta M{r_e}^2}{{M_\odot}^2 s^2}\right)^{1/4} \tag{5}$$

Taking M to be the present mass of the Earth, the necessary conditions for capture are given in Fig. 2 for various values of $\Delta M/M$. It is seen that there is a well defined capture window even for small mass increments. This capture window corresponds to the condition of low relative velocity when $\varepsilon \approx s/r_e$.

Clearly the above analysis is highly idealised. The influences of a finite rate of mass addition and of the gravitational attraction of the Sun should be considered. The analysis does, however, indicate the possible importance of accretional capture, and indicates that further studies should be carried out.

Petrogenesis of eucrite, howardite and diogenite meteorites

THE mineralogical, textural and compositional characteristics of the eucrite meteorites suggest that they are the products of igneous processes. Howardites are polymict breccias containing a variety of fragments, the bulk of which are thought to have crystallised from eucrite and eucrite-related melts[1]. Diogenites are orthopyroxene-rich stones which may represent cumulates from eucrite-related melts[2]. I relate here experimentally determined phase equilibria to the igneous processes which produced the eucrites and their associates.

I conducted melting experiments on a sample of the Juvinas eucrite (Harvard 87) at 1 atm total pressure and various oxygen fugacities. Samples were held in iron or molybdenum foil capsules in quenching furnaces with oxygen fugacity controlled by H_2–CO_2 gas mixtures[3]. Phase compositions were determined with an electron microprobe. At $f_{O_2} = 10^{-13.4}$ atmospheres and less than 10 °C below the metal-saturated olivine liquidus (Fo_{67}; 1,183 °C), the sample is saturated with olivine (Fo_{65}), pigeonite (Wo_5En_{65}), plagioclase (An_{94}), chrome-rich spinel and iron metal. On cooling, olivine reacts out by 1,150 °C and a silica polymorph crystallises from 1,085 °C.

Figure 1 is a projection of a low pressure liquidus diagram relevant to eucrite crystallisation. Olivine is in reaction relation with liquids at peritectic *A* (Fig. 1), and on the olivine + pyroxene boundary curve. Eucrite compositions have been projected onto this diagram. The clustering of non-cumulate eucrite compositions about the olivine + low calcium pyroxene + plagioclase + chrome spinel + metal peritectic (*A*, Fig. 1) indicates that like Juvinas, these other eucrites are probably multiply saturated near their liquidi. This emphasises the role of low pressure crystal–liquid equilibria in the genesis of the eucrites: all known eucrites can be designated as either multiply saturated liquids at *A* (Fig. 1) or cumulates or partial cumulates of the pyroxene and plagioclase near the liquidi of such liquids. Any model of the igneous processes which produced the eucrites must account for this preferential generation of liquids at peritectic *A* (Fig. 1).

The compositions of pyroxenes produced in the Juvinas experiments are similar to the compositions of pyroxenes in

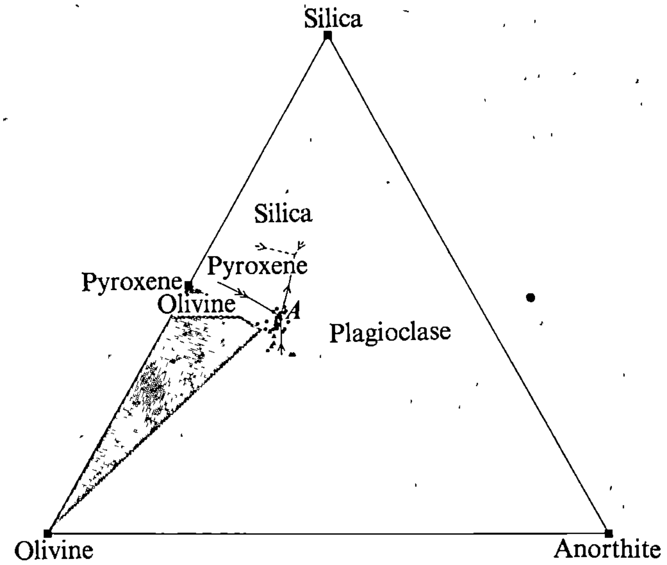

Fig. 1 Projection of low pressure liquidus diagram valid for molar Fe/Fe+Mg ≈ 0.60. Field boundaries were located by microprobe analyses of multiply saturated liquids from experiments on the Juvinas eucrite. Iron metal and chrome-rich spinel are present in all fields. ▲, Projected analyses of cumulate eucrites: Moore County (2 analyses), Serra de Magé (2 analyses), Moama, Medanitos; ●, Projected analyses of other eucrites. Pre-1960 analyses are plotted only when a more recent analysis of the same stone is not available. Analyses are plotted on this diagram by recalculating SiO_2, Al_2O_3, FeO, MgO, CaO, Na_2O and K_2O in terms of molar SiO_2, $CaAl_2Si_2O_8$, Fe_2SiO_4, Mg_2SiO_4, $CaSiO_3$, $NaAlSi_3O_8$ and $KAlSi_3O_8$ and then projecting on to the olivine–anorthite–silica plane. Analyses which plot below the pyroxene–plagioclase join do so because of the effects of modal iron metal, troilite, chromite, ilmenite and calcite on the projection. *A* and the shaded region, are explained in the text.

cumulate and non-cumulate textured eucrites and to those of many pyroxenes in howardites, but are more Fe-rich than the pyroxenes and olivines in diogenites and the most magnesian pyroxenes and olivines in howardites. These natural Mg-rich phases would have equilibrated with liquids more magnesian than the eucrite magmas at *A* (Fig. 1), and any model of eucrite petrogenesis should account for the existence of such liquids.

Reduction of eucrite magma resulting in crystallisation of iron metal and a decrease in the Fe/Mg and Fe/Mn of the magma could produce magmas which would crystallise magnesian diogenitic and howarditic pyroxenes. The pyroxenes crystallised from such liquids would have a higher Mn/Fe than those crystallised from unreduced eucrite magmas. Such an origin for diogenitic and the most magnesian howarditic pyroxenes is, however, unlikely since the Mn/Fe ratios of these phases are nearly identical to those of pyroxenes in cumulate and non-cumulate eucrites and of the more iron-rich howarditic pyroxenes[2,4].

Models which produce eucrite liquids by the differentiation of magnesian parental magmas and which invoke the fractional crystallisation of eucrite magmas to explain the bulk of the chemical variation observed in eucrites[2] encounter several difficulties. First, as pointed out in connection with Fra Mauro rocks and soils, which display a similar clustering about an olivine + plagioclase + low calcium pyroxene peritectic, it is difficult to preferentially generate liquids at peritectic *A* (Fig. 1) by low pressure differentiation of other magmas through the action of crystallisation processes[5]. Second, if the proposed parental magmas ever passed through a stage in their evolution in which pyroxene was the only crystallising phase (required by such models to produce the diogenites and magnesian pyroxenes in howardites), the liquid lines of descent of such magmas would never encounter the peritectic at *A* (Fig. 1). Third, low pressure fractional crystallisation paths which can produce liquids at *A* (Fig. 1) involve the crystallisation of plagioclase and olivine, but not of pyroxene. At low oxygen fugacities, the fractionation of plagioclase would rapidly differentiate europium from the other rare earth elements. Models which attempt to derive magmas at peritectic *A* (Fig. 1) by the low pressure fractional crystallisation of more magnesian magmas are, therefore, not easily reconciled with the primitive rare earth distributions of some eucrites[6], the existence of diogenitic and howarditic pyroxenes more magnesian than the pyroxenes at the liquidi of magmas at *A* (Fig. 1), or the rarity of olivine in diogenites, howardites and eucrites. Fourth, these models cannot easily reconcile the constancy of the major element chemistry (particularly the Fe/Fe+Mg ratios) of eucrites which cluster at *A* (Fig. 1) with their variations in rare earth and incompatible element concentrations[6]. Though the variations in the concentrations of rare earths and incompatible elements in the eucrites at *A* (Fig. 1) apparently suggest that these eucrites could be related to each other through the fractional crystallisation of up to 60% of a liquid of the composition of Haraiya[2] (another eucrite which projects at *A* (Fig. 1)), that suggestion is incompatible with the fact that all of these eucrites have nearly identical major element chemistries. A liquid which has reached *A* (Fig. 1) will not remain there during fractional crystallisation; as it loses heat it will change composition along the pyroxene + plagioclase cotectic and trend toward iron enrichment. Fifth, if these models are valid, the total volume of the magnesian parental magma must have greatly exceeded the volume of eucrite magma. Examples of magmas more primitive than the eucrites should predominate among falls and the distribution of fragments in howardites should be strongly skewed toward the products of magmas more magnesian than the eucrites at peritectic *A* (Fig. 1). These relationships are not observed.

I propose the following model to account for the observed features of the eucrites and their associates. The eucrite magmas at the peritectic *A* (Fig. 1) are interpreted as the products of small degrees of low pressure partial melting of an olivine + low calcium pyroxene + plagioclase + chrome spinel + iron metal source which projects in the shaded region of Fig. 1. Compositional variation of the eucrites is the result of variable degrees of partial melting and subsequent fractional crystallisation and crystal accumulation. Diogenites are regarded as cumulates of phases separated from more advanced partial melts of the same source. Howardites are polymict breccias containing fragments sampling the spectrum of differentiated liquids and cumulates developed from the range of primary magmas produced by variable degrees of partial melting of this source.

Eucrite magmas produced by the partial melting of such a source would plot at the peritectic *A* (Fig. 1) until plagioclase was exhausted from the source region; this explains the observed clustering of eucrite compositions. If the eucrites represent small degrees of partial melting, variations in the degrees of partial melting which produced different eucrite liquids could have produced the significant variations in the concentrations of incompatible elements which are observed between eucrites of indistinguishable major element chemistry and Fe/Fe+Mg ratios[6]. If plagioclase becomes exhausted from the source region at small degrees of partial melting, this model can also explain the variations in rare earth distributions and the magnitudes of europium anomalies which are observed between eucrites of nearly identical major element chemistry[6].

The subsequent crystallisation and separation of pyroxene and plagioclase from the primary magmas at *A* (Fig. 1) would be expected to produce cumulates and silica and incompatible element enriched liquids of higher Fe/Fe+Mg ratios projecting near the pyroxene + plagioclase cotectic emanating from *A* (Fig. 1). Moore County and Serra de Magé are examples of these cumulates[1]. The bulk chemistry and mineralogy of Binda, considered by some to represent a magma parental to the eucrites[2], are compatible with such a cumulate origin. Nuevo Laredo and

Lakangaon may represent liquid differentiates from the crystallisation of magmas at *A* (Fig. 1). Both are enriched in incompatible elements and display the iron enrichment expected in differentiated liquids. It is unlikely that they represent smaller degrees of partial melting of the same source that produced the eucrites which are not iron enriched, for at least in the case of Nuevo Laredo, rare earth distributions are not compatible with this interpretation[6]. Other eucrites may have been affected to a lesser extent by fractional crystallisation.

Though olivine would be present in the source rock and the residue left after melting, it would not be present at the liquidi of the partial melts at *A* (Fig. 1), (provided there was little fall in pressure accompanying eruption) because it is in reaction relation with these liquids. This is consistent with the absence of olivine in eucrites and its rarity in howardites.

If the reaction relationship between iron metal and silicate liquids observed in synthetic systems[7] extends to this natural system, metal would remain in the source region until all crystalline silicate phases were removed by melting. The probable reaction relation between chrome-rich spinel, low calcium pyroxene and liquid[8] suggests that chrome spinel would remain in the source region until all the pyroxene had been removed by melting.

In conditions of fractional fusion[9], the production of magma by further melting would be nearly halted after the exhaustion of plagioclase from a source projecting in the shaded region of Fig. 1. If equilibrium fusion or imperfect fractional fusion took place, the melts produced after the exhaustion of plagioclase from the source would move up the olivine + pyroxene curve (Fig. 1), continuously decreasing the Fe/Fe+Mg ratio, until pyroxene was exhausted from the source. The diogenites and magnesian pyroxenes in howardites can be interpreted as cumulates of the pyroxene crystallising near the liquidi of these more advanced partial melts. The rarity of olivine in these meteorites is predicted since these liquids would not ordinarily crystallise olivine. The occasional presence of olivine in these meteorites (and Chassigny) could result from variations in source composition, variations in conditions of melting or crystallisation (for example, a small drop in pressure between the source region and the environment of crystallisation), or xenocrysts from the imperfect separation of the magma from the source. The absence of cumulate plagioclase in the diogenites or in intergrowths with the most magnesian howarditic pyroxenes[4] can be expected since plagioclase would not be present at the liquidi of these magmas.

The residue left in the source region after the exhaustion of plagioclase by partial melting would be olivine + low calcium pyroxene + chrome spinel + metal. If metal were a major constituent of the source, this residue would approximate the Lodran meteorite[10]. If the source were low in metal, the olivine-bearing diogenites could represent such residues. Since such an origin is not possible for the olivine-free diogenites, a cumulate origin is preferred for the entire diogenite group.

Further equilibrium fusion or imperfect fractional fusion of this same source after the exhaustion of pyroxene from the source region would produce liquids moving away from the olivine + pyroxene reaction curve (Fig. 1) towards the olivine composition, leaving a pallasite-like residue of olivine + chrome spinel + metal. The olivines crystallised near the liquidi of such melts may account for some howarditic and diogenitic olivines.

The abundance patterns of fragments in howardites[4] and the lack of known meteorites with compositions which could represent partial melts more advanced than the eucrites at *A* (Fig. 1) are consistent with the bias toward the products of smaller degrees of partial melting which is expected in conditions of imperfect fractional fusion.

Though eucrite liquids would have equilibrated with the metal of the residue left in the source region after partial melting, metal would not be at the low pressure liquidi of these melts because of the probable reaction relation between metal and silicate liquid (provided no change in oxidation state of the magmas occurred between the source region and the environment of crystallisation). This is compatible with both the observed low Ni contents of the eucrites, which suggest they have equilibrated with metal, and the petrographic observations that metal is never found as a cumulate phase in diogenites and cumulate eucrites, is rarely enclosed in pyroxenes, and is usually a late, interstitial phase when it occurs[11]. The late stage crystallisation of metal in eucrites could be attributable to desulphurisation processes similar to those which have been proposed to account for metal in lunar mare basalts[12].

A partial melting model requires a suitable low pressure source assemblage in the eucrite parent body. A primitive type of mesosiderite (perhaps a condensate[13] or the product of early differentiation and brecciation on the eucrite planet or on some other body which was subsequently incorporated into the eucrite planet) could be suitable source material. The low pressure mineralogy (< 8 kbar) of the bulk composition of the eucrite parent body calculated by Wänke and Palme[14] is similar to the source assemblage required by this model. This similarity raises the possibility that the eucrites may have formed by partial melting of the primitive material of the eucrite parent body at 4.6×10^9 yr BP.

I thank Professor Frondel for the sample of Juvinas, the Marshall Aid Commemoration Commission for financial aid, and Professor M. O'Hara, Dr R. Hutchison and Dr C. Ford for discussions and criticism.

Does metallic ammonium exist?

THE ammonium ion NH_4^+ behaves in many ways like an alkali metal ion. This led Ramsey[1] to propose that monovalent ammonium metal (NH_4^+ ions immersed in an almost uniform, degenerate sea of electrons) is stable at pressures much lower than typical insulator–metal transition pressures[2] of megabars $\sim 10^{11}$ Pa (10^5 Pa = 1 bar). Subsequently, it was estimated[3] that the transition from a mixture of NH_3 and H_2 molecules to metallic ammonium, occurs at a pressure of less than 2.5×10^{10} Pa. If this estimate were correct, metallic ammonium would be of great interest to experimental high pressure physicists, and to planetary physicists. Indeed, metallic ammonium has been invoked in some[4,5] but not all models for the interiors of Uranus and Neptune; and its existence could be of importance[6] for calculations of the interior magnetic fields of these planets.

Here I report new calculations which demonstrate, rather conclusively, that metallic ammonium, at least in the form envisaged by Ramsey, is unstable at all pressures. My calculations disagree with those of ref. 3 in two important respects: first, I find that the insulating NH_3–$\frac{1}{2}H_2$ mixture is sufficiently compressible to remain the favoured phase, at least until pressures of $\sim 10^{11}$ Pa, even if the metallic phase calculation of ref. 3 is correct. Second, my calculation for the metallic phase gives a systematically higher energy than was obtained in ref. 3. These results are summarised in Fig. 1.

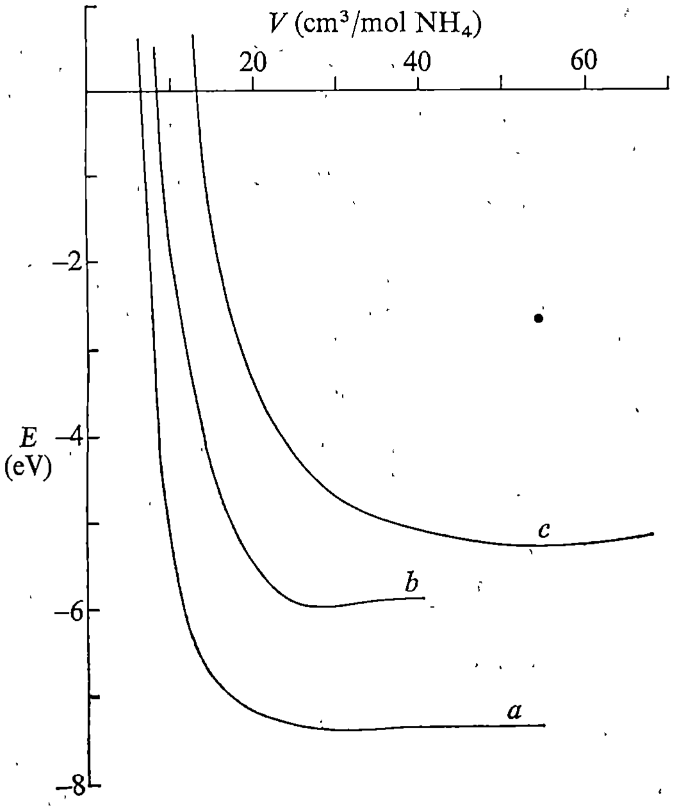

Fig. 1 A comparison of the energy–volume relationships for molecular NH_3–$\frac{1}{2}H_2$ (*a*) and metallic ammonium (*b*, ref. 3; *c*, my results).

The equation of state for the NH_3–$\frac{1}{2}H_2$ mixture was calculated assuming volume additivity, so that $V(P)$, the specific volume of the mixture at pressure P, is given by

$$V(P) = V(NH_3,P)+\tfrac{1}{2}V(H_2,P) \qquad (1)$$

where $V(NH_3,P)$ and $V(H_2,P)$ are the molecular volume–pressure relations of ammonia and hydrogen solids, respectively. The equation of state for ammonia is known at low pressures ($P < 2\times10^9$ Pa) from experiment[7], and at very high pressures ($P \gtrsim 2\times10^{11}$ Pa) from Thomas–Fermi–Dirac theory[8]. The intermediate region is estimated by interpolation, but the uncertainties in volume do not exceed $\sim$ 15%. The equation of state for hydrogen is taken from Ross's analysis[9] of the Livermore shock data. From $V(P)$, the energy of the mixture is evaluated:

$$E(P)-E(0) = -\int_0^P P'\frac{dV(P')}{dP'}dP' \qquad (2)$$

at $T = 0$ °K. In Fig. 1, the energy zero is chosen to be the energy of infinitely dispersed NH_4^+ ions and electrons. Thus,

$$E(0) = -(\tfrac{1}{2}D+I_H-A_p+B) \qquad (3)$$

where $D = 4.44$ eV is the dissociation energy of the hydrogen molecule, $I_H = 13.54$ eV is the ionisation energy of the hydrogen atom, A_p is the proton affinity of the ammonia molecule, and $B \sim 0.1$ or 0.2 eV is the binding energy of the NH_3–$\frac{1}{2}H_2$ crystal mixture. The most likely value of A_p is 8.6 eV (ref. 10), but the error in this figure could be as much as 0.3 eV. This gives $E(0) = -7.3$ eV. The resulting energy–volume relation is shown in Fig. 1. Even allowing for the uncertainties in A_p and $V(P)$, the curve never crosses the metallic phase curve of ref. 3. Their transition pressure estimate is invalid since they did not calculate the NH_3–$\frac{1}{2}H_2$ equation of state, but merely constructed that tangent to the metal-phase curve which passes through the molecular-phase zero pressure point.

It must be emphasised that my conclusion is not contingent on the validity of volume additivity (equation (1)). My calculation is correct for a conceivable state: a mixture of macroscopic crystals of pure NH_3 and H_2. If an alloy is preferentially formed it can only have lower energy than the calculation predicts—this would make the molecular phase even more favourable.

Since the NH_4^+ ion is about the same size as the Rb^+ ion, simple pseudopotential theory[11] would lead us to expect that the equilibrium ($P = 0$) volume per ion of metallic ammonium is comparable with that of rubidium. The detailed calculations confirm this prediction of the simple (but very successful) pseudopotential theory. In contrast, an equilibrium volume was found in ref. 3 that was about a factor of two smaller, and more comparable to metallic sodium. My calculation is based on the Wigner–Seitz approach, but with the potential given by the self-consistent density-functional theory of Kohn and Sham[12], which includes all exchange and correlation effects in a local but self-consistent approximation. The Bardeen perturbation theory[13] was used to evaluate the effective (band) mass of the conduction electrons.

The method was tested on metallic sodium, and the results were −6.38 eV for the total energy per ion, and $3.96a_0$ for the radius of the Wigner–Seitz sphere (where $a_0 = 1$ Bohr $= 0.529\times10^{-8}$ cm); these are in excellent agreement with the observed values[12] of −6.27 eV and $3.93a_0$, respectively. For metallic ammonium, I used the spherical potential of ref. 3 and also their core wavefunctions. The results were −5.40 eV for the energy and $5.18a_0$ for the radius, whereas they obtained −5.84 eV and $4.23a_0$, respectively. I also made a calculation using more accurate core wavefunctions[14] and a correspondingly larger N–H bond length ($1.91a_0$ instead of $1.84a_0$), obtaining −5.36 eV and $5.35a_0$ for $P = 0$. The corresponding energy–volume relation is the upper curve in Fig. 1. At high pressure, the energy probably rises even more rapidly than shown, because of the Born–Mayer repulsion between the ion cores. Corrections for the non-spherical symmetry of the NH_4^+ ion have been estimated and are negligible at low pressures.

I conclude that monovalent metallic ammonium is never the thermodynamically favoured phase for an NH_3–$\frac{1}{2}H_2$ mixture. Of course, this mixture must eventually become metallic if compressed enough, but this would not occur until pressures of $\sim 10^{11}$ Pa. The very compact metallic phase that would then form is unrelated to the low density metallic phase proposed by Ramsey.

I notice, finally, that a dynamo-generated magnetic field in Uranus or Neptune is not contingent on the existence of metallic ammonium—other sources of electrical conductivity may be adequate (this will be dealt with elsewhere).

Discussions with N. W. Ashcroft and J. A. Krumhansl are acknowledged, as is the support by grants from the US National Science Foundation and NASA.

Mercury in the Kuroshio and Oyashio regions and the Japan Sea

ALTHOUGH measurements of the mercury concentration in sea water have been made by several investigators[1–13], the reported values are widely scattered and it may be significant that almost all the samples were kept in polyethylene bottles after acidification. Weiss *et al.*[14] have reported that the main source of mercury in the oceans was the degassing of the Earth's crust by way of the atmosphere. It should then be supposed that the large experimental variations for open oceans does not reflect the true situation.

One source of error is to be found in the use of polyethylene bottles—we found that nanogram amounts of mercury were leached out of the plastic by the samples, whose mercury concentrations increased by factors of 2 to 100, even if the bottles had been washed out with nitric or hydrochloric acid before use. The outline has already been reported[15], and the detailed results will be published elsewhere. Recently, sample contamination by polyethylene bottles has been confirmed[16,17]. In our work, glass bottles and stoppers, which had been checked to be non-contaminating beforehand, were used for sample storage.

Here we report on the mercury concentrations in the Kuroshio and Oyashio regions and the Japan Sea. Samples were collected with Nansen bottles from February to August 1974. Immediately after collection, the water was acidified to 0.4 N with sulphuric acid, and stored in a glass bottle. The samples were analysed at the laboratory after a month's storage.

The outline of the analytical method is as follows[18]. Ionic mercury, in a 0.5–0.8-l sample solution, is reduced with stannous chloride, and the mercury vapour released is flushed out with nitrogen on to gold particles packed in a glass tube. The metal is then heated at 500 °C in a furnace, and the vaporised mercury is determined using an atomic absorption spectrophotometer. The error in a single determination was ~ 10% when measuring quantities of ~ 5 ng Hg.

The results are shown in Table 1. Although there were haloclines and thermoclines in the seas at our sampling points, no appreciable change of mercury concentration with depth was found, and the samples showed an almost constant value, 5.0 ± 0.5 ng l^{-1}.

According to Fitzgerald *et al.*[12], if the seawater samples had been stored in plastic bottles, at *p*H 1, for 10 days, the mercury concentrations would have been 57% lower than those in samples measured immediately, which they therefore did—on board their ship.

We found, however, that for sea water of more than 30‰ salinity, the mercury concentrations were 30% higher than in the samples measured immediately. We believe that the discrepancy arises because of the presence of some mercuric complexes, whose mercury cannot be detected immediately. Acidification to 0.4 N with sulphuric acid for two weeks at room temperature (and longer at lower temperatures) is required to release this mercury, and give the correct total mercury concentration. (For samples with salinities of less than 30‰, the mercury concentration actually decreases, because of adsorption to the glass walls.)

We thank Mr H. Hamada of Seikai Regional Fisheries Research Laboratory and the staffs of Hakodate Marine Observatory, Toyama Prefecture Fisheries Experimental Station and Nagasaki Prefecture Fisheries Experimental Station for sampling the water and measuring the temperature and salinity.

Model for the accumulation of radionuclides in oysters and sediments

THE time variation of the concentration of γ-ray emitting radionuclides has been measured and modelled in a stable population of American oysters (*C. virginica*), and associated estuarine sediments. Radionuclide concentrations were measured for the natural radionuclides ^{212}Pb and ^{40}K and for the man-made radionuclides ^{58}Co, ^{60}Co, ^{54}Mn, ^{95}Nb, ^{134}Cs and ^{137}Cs using a Ge(Li) detector with a massive lead shield and multichannel analyser. Measured concentrations of the most abundant man-made radionuclides observed in this study (^{58}Co, ^{60}Co, and ^{54}Mn) were compared with concentrations calculated with a mathematical model for the accumulation and loss of these radionuclides by oysters and sediments.

Much work has been done in recent years in the accumulation of radionuclides in marine organisms (refs 1 to 4, and references therein). Mathematical models for accumulation and loss of radionuclides are usually based on laboratory studies using a constant source of radionuclides, a condition which is generally convenient. A model for field studies, however, must provide for the time variation of the source of radionuclides, since in the case of nuclear reactors the liquid radionuclide effluent is usually released according to some schedule with various waiting periods between releases, as discussed by Heft *et al.*[2]. This time variation of source intensity can be included in the mathematical model by driving the first order linear differential equation for accumulation and loss with a time varying function representing the release schedule. This model corresponds mathematically to a driven system with characteristic relaxation times for the various mechanisms of accumulation and loss.

American oysters *C. virginica* were reared at four locations at the Montsweag Estuary of the Sheepscot River in southern-central coastal Maine, USA and at a control site six miles east on the Damariscotta River Estuary.

At two month intervals, ~1 kg of live oysters from each site were randomly selected from a larger population of the same age and size. Each sample was removed from its rearing tray, transported to the detector, γ-ray counted in a standard geometry for 5,000 s, and returned to its site. The resulting counts were computer processed using the Compton continuum subtraction method[5]. The concentrations of radionuclides were determined using standard techniques to calibrate the multichannel analyser–detector–shield system.

Sediments were collected at the same five sites by removing the first centimetre of sediment over an area of sufficient size to provide a 2 kg (wet) sample. Concentrations of radionuclides in the sediments were measured in the same manner as the oysters.

The uptake of radionuclides may be described by a first order linear differential equation

$$\mathrm{d}N/\mathrm{d}t = -\lambda N + R(t), \tag{1}$$

where $\mathrm{d}N/\mathrm{d}t$ is the change in atoms of radionuclide, λN is the rate of loss due to radioactive decay, and $R(t)$ is the rate of introduction of radionuclide from an external source (the nuclear reactor release schedule)[6]. Depuration, or biological loss, may be included by writing a 'lambda effective' as the sum of the radioactive decay constant and a biological decay constant.

The solution to equation (1) may be written

$$N = \exp(-\lambda t)\int^{t} R(\tau)\exp(\lambda\tau)\mathrm{d}\tau + c\exp(-\lambda t) \tag{2}$$

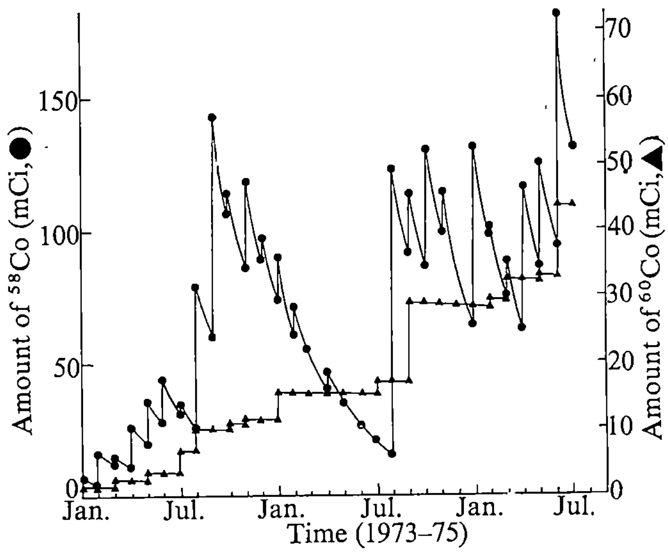

Fig. 1 ●, Theoretical accumulation of ^{58}Co in mCi for the case $U = 1\ \mathrm{g}^{-1}$ plotted against month of year from February 1973 through June 1975. ▲, Theoretical accumulation of ^{60}Co in mCi for the case $U = 1\ \mathrm{g}^{-1}$ against month of the year from February 1973 through June 1975.

We assume that releases of radionuclides are made in a sequence of m times, $\{t_1, t_2, t_3, \ldots .t_m\}$ and the amount of nuclide released is given by a function $f(t)$ where

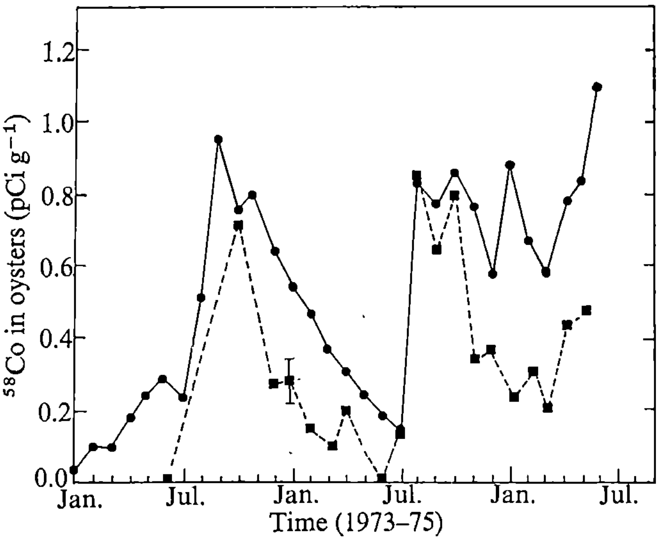
$$f(t) = f_1\delta(t-t_1) + f_2\delta(t-t_2) + \ldots . f_m\delta(t-t_m)$$

The amount of radionuclide release by the reactor and retained by the sample is given by U, so that, assuming U is a constant, we can construct a solution for the intervals between the times of release.

$$\begin{array}{ll} 0 \le t \le t_1 & N(t) = c\mathrm{e}^{-\lambda t} \\ t_1 \le t \le t_2 & N(t) = Uf_1\mathrm{e}^{-\lambda(t-t_1)} + c\mathrm{e}^{-\lambda t} \\ t_2 \le t \le t_3 & N(t) = Uf_2\mathrm{e}^{-\lambda(t-t_2)} + Uf_1\mathrm{e}^{-\lambda(t-t_1)} + c\mathrm{e}^{-\lambda t} \\ \cdot & \cdot \\ \cdot & \cdot \\ \cdot & \cdot \end{array} \tag{3}$$

The interpretation of this set of equations is obvious. Sudden increases occur at each time of release. Typically, the radionu-

Fig. 2 ■, Measured ^{58}Co radionuclide concentration in oysters at the reactor outflow site. A typical 1σ error bar is shown. ●, Theoretical curve for ^{58}Co scaled by factor $U = 7.6\times10^{-12}\ \mathrm{g}^{-1}$ against time in months for the years 1973–1975.



clides are released weekly, over a period of a few hours. For the purposes of illustrating the theory presented here, however, it has been found sufficient, for a bi-monthly sampling schedule, to approximate the actual release schedule with a monthly release in which the total amount of each radionuclide released is assumed to be released instantaneously. Graphs of two typical cases are shown in Fig. 1, which illustrates the results for ^{58}Co (half life 2.4 months) and ^{60}Co (half life 63 months).

The radionuclide concentration for ^{58}Co in oysters expressed in pCi g^{-1} is shown in Fig. 2. The broken line represents the experimental values for this radionuclide at the reactor outflow site and the theoretical results are shown with a solid line. The peaks found in the theory are evident at the reactor outflow as well as the other three Montsweag Estuary sites. In general it is shown that the oysters exhibit a faster decrease in activity than predicted by the radioactive decay constant only. An effective decay constant taking into account the biological decay constant as well can bring the theory into better agreement with experiment.

The concentration of the radionuclide ^{54}Mn for the reactor outflow site was found to be practically constant with time and compares favourably with the theoretical prediction. In addition to ^{58}Co and ^{54}Mn small amounts of ^{60}Co were observed, while the amount of naturally occurring radionuclide ^{40}K varied in time with the salinity at each site.

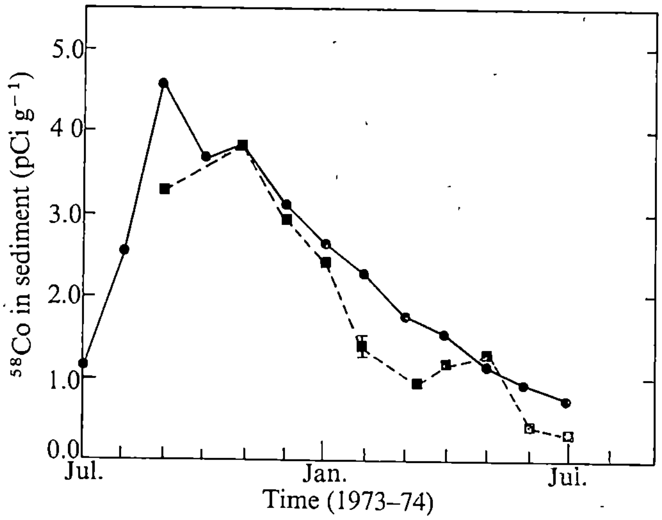


Fig. 3 ■, Measured ^{58}Co radionuclide concentration in sediment at the reactor outflow site. A typical 1σ error bar is shown.. ●, Theoretical curve for ^{58}Co scaled by factor $U = 31 \times 10^{-12}$ g^{-1} against time in months for the years 1973–1974.

The concentration of the radionuclide ^{58}Co in sediments is shown in Fig. 3. The broken lines represent the experimental values for this radionuclide and the solid line represents the theory. Again the decrease of ^{58}Co is more rapid than theory predicts, and in this case represents loss of radioactivity from the sediments by primarily physicochemical transport. The other three estuary sites had a factor of 10 less radionuclide than this particular site, but showed very similar variations with time.

Experimental measurements of sediments continued monthly after July 1974. These results are not, however, comparable with theory after this time because extensive construction in the estuary has temporarily changed and complicated the sedimentation.

For the sediments site at the outflow we observe the natural radionuclides ^{40}K and ^{212}Pb having average concentrations 5.7 pCi g^{-1} and 0.4 pCi g^{-1} respectively. We also observe the man-made radionuclides ^{58}Co, ^{60}Co, ^{54}Mn, ^{137}Cs, ^{134}Cs and ^{95}Nb with average concentrations of 4.9, 0.8, 0.2, 0.2, 0.4 and 0.8 pCi g^{-1}, respectively. These concentrations are presented to give a comparison of the natural and man-made radionuclides observed.

Since the theoretical and observed time dependence factors seem to agree, it is possible to divide the sample concentration (pCi g^{-1}) at each site by the release of radionuclides from the reactor (Ci) to form a measured uptake ratio U. The U values for ^{58}Co in oysters at the different sites in order of increasing distance from the outflow were 7.6, 5.6, 2.6 and 1.3, where the units of U are $g^{-1} \times 10^{-12}$. These U values indicate most of the ^{58}Co is concentrated in the region of the outflow site decreasing rapidly with distance from the reactor. The U values of the other isotopes (^{60}Co and ^{54}Mn) show the same trend, both in the oysters and sediments. A first principles calculation of U values, which has not been done, must take into consideration the reactor radionuclide effluent inventory; the concentration factors for the uptake medium, and the physical oceanography[7] of the estuary.

Disordered drinking after abdominal vagotomy in rats

WHILE investigating the effect of abdominal vagotomy on satiety elicited by cholecystokinin[1], we noted that many vagotomised rats seemed to be undernourished and failed to regain their preoperative weight. Because of their low water–food ratio (vagotomised 1.3±0.5 ml g^{-1}, sham 1.8±0.1 ml g^{-1}, $P < 0.001$), we analysed their drinking behaviour in various conditions. We report here that abdominal vagotomy produces severe deficits in drinking behaviour that can be characterised as motivational.

Bilateral vagotomy was performed along the lower oesophagus in nine male rats (430–560 g) under Equithesin (Jensen–Salsbery Laboratories) anaesthesia. Sham vagotomy (manipulation of the oesophagus without nerve transection) was carried out in ten rats. Vagotomy was verified anatomically at the conclusion of the drinking tests without knowledge of the behavioural results. All nine vagotomised rats were completely disconnected.

Rats were housed individually, maintained on a 12-h light–dark cycle with continuous access to Purina pellets and tapwater except during drinking tests, when food was removed. Food and water intakes were measured daily for 1 week before and for 2 months after surgery. Drinking tests began 1 month after surgery when daily food and water intakes had stabilised.

Vagotomised rats drank much less water than sham rats during 24 h when no food was available (vagotomised 1.8±0.4 ml per 100 g body weight (BW), sham 6.1±0.8 ml per 100 g BW, $P < 0.001$; control data, Fig. 1). After 24 h water deprivation (with food available), vagotomised rats drank as much in 2 h as sham rats (vagotomised 2.4±0.3 ml per 100 g BW, sham 2.9±0.1 ml per 100 g BW) although five of the nine drank less than the smallest intake of sham rats. Vagotomised rats did not drink normally (Fig. 1) in the 2 h after cellular dehydration was produced by hypertonic saline

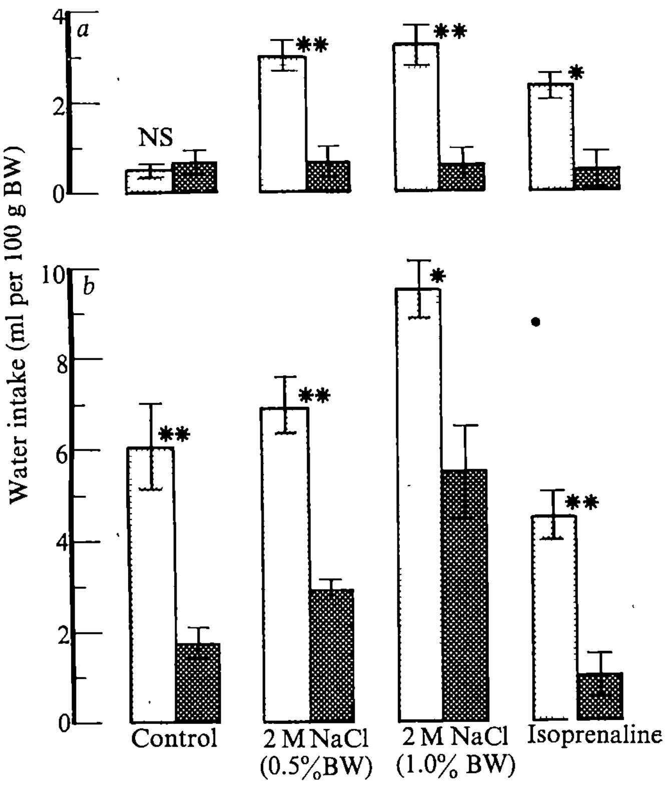

Fig. 1 Water intake (± s.e.) for sham (light bars) and vagotomised (dark bars) rats in 2 h (*a*) and 24 h (*b*) after NaCl or isoprenaline (0.16 mg per kg BW). There were at least eight rats in each group in control and NaCl conditions. There were four vagotomised and five sham-operated rats treated with isoprenaline. Variance is expressed as s.e. All statistical comparisons were made with a two-tailed *t*-test. NS, Not significantly different; * $P < 0.01$; ** $P < 0.001$.

(2 M NaCl, 0.5 or 1.0 ml per 100 g BW, intraperitoneally). The deficit was severe: two of the nine did not drink after 0.5% BW NaCl (0.5 ml per 100 g BW) and five did not drink after 1.0% BW NaCl (1.0 ml per 100 g BW). None of the lesioned rats seemed depressed by the saline load.

Four hours after salt loading, vagotomised rats still drank less (unpublished data), but by 24 h their intake above control was equal to that of sham rats (Fig. 1). These 24-h intakes should not be interpreted as drinking in response to intracellular dehydration alone, because urinary excretion of solute load probably also led to extracellular dehydration.

In response to isoprenaline[2], vagotomised rats also failed to drink normally: three did not drink and the other two drank less and had longer latencies than sham rats (Fig. 1).

Polyethylene glycol also elicits drinking through extracellular[3] and possibly intracellular[4] stimuli. Five vagotomised and four sham-operated rats were injected with polyethylene glycol (5 ml of 30% w/w solution in 0.9% NaCl, subcutaneously) and immediately offered water. After 8 h, three of five vagotomised rats had not drunk. By 24 h, however, all rats had drunk, but group intakes differed significantly (vagotomised 12±2.6 ml, sham 22±2.0 ml, $P < 0.02$). When NaCl (0.9%) was offered to drink 24 h after injection of polyethylene glycol, all rats drank large volumes in the 1-h test (vagotomised 38.4±9.2 ml, sham 34.6±5.7 ml). The normal intake of saline and the low intake of water after polyethylene glycol demonstrates that the effect of vagotomy on water intake cannot be due to painful or uncoordinated oesophageal movements.

In summary, bilateral abdominal vagotomy abolished the drinking response to acute cellular dehydration and to isoprenaline, decreased drinking in the absence of food and after polyethylene glycol, decreased the water–food ratio, and tended to decrease drinking after water deprivation. Transection of both vagal trunks seems to be necessary for these deficits, because drinking was normal in 2 rats with a large vagal connection persisting between oesophagus and stomach (unpublished). The critical region of vagal innervation that must be removed to obtain the drinking deficits was not determined, but the level of section preserved the vagal innervation of the liver and portal bed, which should have permitted normal function of postulated hepatic osmoreceptors[5].

Such experiments have not been reported before in rats, but the effect of vagotomy on thirst has been studied extensively in the dog. The results are different and seem to depend on the level of vagal section: abdominal vagotomy increased the size of a bout of drinking, but did not alter the 24-h water–food ratio[6]; thoracic vagotomy did not change the drinking response to hypertonic saline[7], but cervical vagosympathectomy enhanced drinking to hypertonic saline[8] and blocked the ability of extracellular dehydration (haemorrhage) to decrease the osmotic threshold for drinking to hypertonic saline[8]. This last effect is consistent with the decreased responses to the extracellular challenges of isoprenaline and polyethylene glycol reported here, but none of this work in the dog predicts the failure of drinking after hypertonic saline that we found.

It is not likely that these drinking deficits result from the removal of efferent vagal influence, because peripheral anticholinergic block produced by methylatropine or methylscopolamine does not diminish drinking after hypertonic saline[9,10] or water deprivation[11]. Furthermore, the peripheral and central anticholinergic effects of atropine do not block drinking after isoprenaline[2].

If peripheral anticholinergic block mimics all the effects of removal of vagal efferent function, then the failure of anticholinergics to reproduce the effects of abdominal vagotomy on drinking suggests that the critical lesion is the loss of vagal afferent stimuli. The role of vagal afferent stimuli from the abdominal viscera in mediating thirst is not known. Fitzsimons[12] has suggested the importance of vagal afferent stimuli, originating in the walls of the great vessels and atria, for eliciting thirst after extracellular dehydration. These regions, however, remained innervated in our vagotomised rats.

Although we do not know if vagotomy abolished pancreatic osmoreceptor[13] or mesenteric vascular volumetric stimulation, the fact that vagotomy abolished or attentuated drinking to a variety of stimuli suggests a deficiency in the motivation for drinking. The clearest example of the decreased responsiveness which characterises this lack of motivation is the drinking behaviour of vagotomised rats during 24 h when food was not present: they drank one-third as much as sham rats (Fig. 1).

In these experiments, the motivational deficit seemed to be restricted to drinking, because the 24-h food intake of vagotomised rats in the absence of water was not different from that of sham rats (vagotomised 3.8±0.3 g per 100 g BW, sham 3.7±0.1 g per 100 g BW). These data are not conclusive, however, and the specificity of the motivational deficit requires more rigorous testing.

Ball reported previously a motivational defect after abdominal vagotomy[14]. He observed elevated thresholds for lateral hypothalamic stimulus-bound eating and self stimulation in vagotomised rats. Ball suggested that this decreased excitability of the lateral hypothalamus after abdominal vagotomy was evidence for the importance of a vago–vagal, positive feedback loop in the mediation of these stimulus-bound behaviour patterns. Our interpretation of the results with drinking behaviour is analogous to Ball's suggestion for feeding and self stimulation.

If the disordered drinking observed after vagotomy were the result of elevated lateral hypothalamic thresholds, lateral hypothalamic damage should produce a similar deficit in drinking. This is confirmed by Stricker[15], who reported that rats recovered from lateral hypothalamic lesions did not drink after polyethylene glycol, ligation of the inferior vena cava or hypertonic saline during relatively brief (1–6 h) testing conditions, but did drink significant amounts of water by 24 h after treatment.

Although the drinking deficits after abdominal vagotomy and lateral hypothalamic lesions seem similar, it remains to be determined if this behavioural similarity signifies an important neurological relationship between afferent vagal stimuli from abdominal viscera and lateral hypothalamic integration of drinking behaviour.

We thank E. M. Blass and A. N. Epstein for critical reading of the manuscript. The research was supported by the Lineberry Fund and a National Institutes of Health research grant and career development awards to J.G. and to G.P.S.

Fast body turns in a cichlid fish

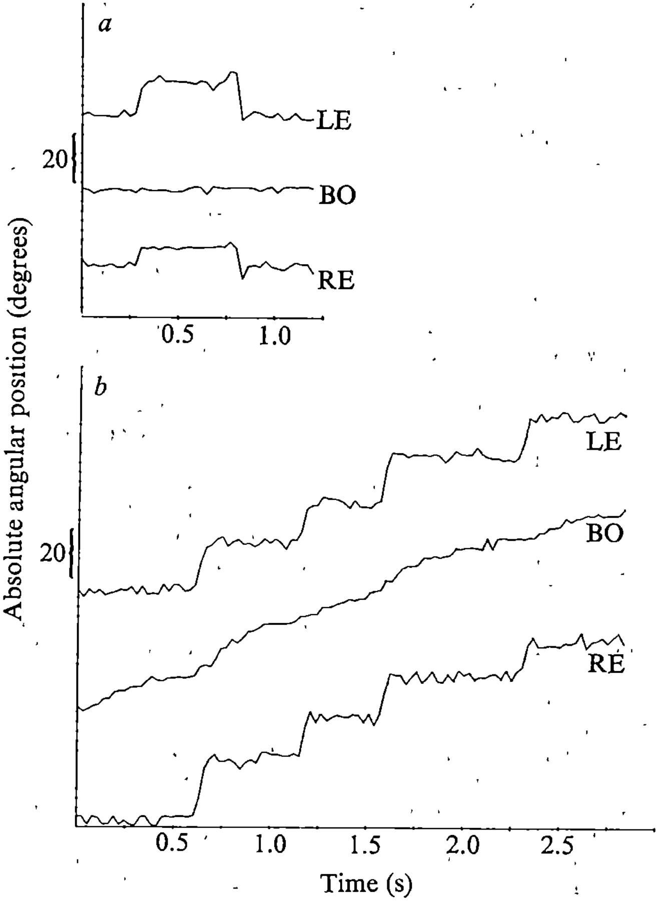
The African cichlid fish *Haplochromis burtoni*, is sexually dimorphic. The female is smaller and of an homogeneous beige colour, whereas the male has bright colour patterns which he can turn on and off quickly. These are important signals, particularly during aggressive interactions[1], since these fish rely extensively, although not exclusively, on visual cues in their social behaviour[2]. Sound production does not seem to be involved[3], but chemical stimuli are important in male–female encounters during reproduction[4]. Colony observations in aquaria have shown that after the disruption of an established social situation, there is considerable behavioural interaction until the new social order is stabilised. Subsequent behavioural interaction is much less frequent, although a rank order is maintained. Since most social encounters seem to depend on visual cues, it seemed likely that vision was involved in the subtle interactions which characterise behaviour in an established social order I have therefore monitored and analysed the horizontal eye movements of male *H. burtoni* during social encounters. I found a new kind of very fast body movement, during which the eyes were held fixed, which are correlated with specific types of behavioural interactions.

Mature male *H. burtoni* (7.0–7 5 cm long) were fitted with eye stalks by an adaptation of Easter's technique[5]. Eye stalks were made from black shrink tubing (0.5 mm diameter × 4.0 mm) by squeezing one end closed with heated tweezers Chewing gently on the stalks for a few minutes softened them so that they could be attached by suction to the upper or rear edge of the fish's cornea. The obstruction to the visual field was 10% or less The fish were placed in a cylindrical Plexiglas tank (50 cm diameter × 15 cm) with a transparent floor. The outer circumference was covered with opaque material, and the tank was illuminated from above through a translucent cover. Normally, three to five fish with eyestalks were filmed from below as reflected in a front-surfaced mirror, with a Super-8 Beaulieu camera at 60 frames s^{-1}. An electronic counter driven by a pulse generator at a known frequency was filmed simultaneously for identification of individual frames and calibration of filming speed.

The data were analysed by projecting the film frame by frame and viewing it through a clear Plexiglas disk with parallel lines etched on it and mounted on a potentiometer. The lines were aligned with the object of interest—an eye stalk or the body position—by rotating the disk. The body position was taken as an axis perpendicular to a line drawn between the two eyes. A voltage proportional to the angle being read was punched on paper tape, which was later fed into a computer (DEC 11/40) and the angular orientation plotted against frame (time). The orientation of the body and of each eye of the fish could thus be measured with respect to the tank for each frame. This angular measurement was repeatable with an accuracy of ±1°.

Three types of motion could be distinguished: eye movements without associated body movements, coordinated eye and body movements (both of which have been described before), and fast body movements with no corresponding eye movements. Figure 1*a* illustrates the first type in which the body remains stationary while the eyes flick rapidly to new positions and, after some time (in this case about 0.5 s), return to approximately their original positions. A typical example of the coordinated eye–body movement is shown in Fig. 1*b* A binocular saccade normally preceded a body turn, and the eyes rotated in the opposite direction relative to the body as turning continued, so that they remained in a nearly constant orientation in space. Both types of eye movement have been described for goldfish[5,6].

Fig. 1 *a*, Absolute angular position of the left eye (LE), body (BO), and right eye (RE) as a function of time. The body remains stationary while the eyes rotate to a new position, returning after 0.5 s. *b*, Coordinated eye–body movement during a slow body turn. In this saccadic eye movement, the eye flicks to new fixation points in space which are maintained as the body turns.



The details of such eye movements in *Haplochromis* and experimental analysis of their control and use will be described elsewhere.

Two examples of the third type of motion are shown in Fig. 2. During these fast body turns, the eyes remain fixed relative to the body. In the first case there are two successive fast turns, both about 40°, separated by 0.2 s. Approximately 0.25 s after the second turn, the animal made a typical saccadic eye movement and corresponding slow body rotation. In the second example, the fish made one large fast turn (105°), followed in 0.1 s by a smaller turn (20°). Approximately 1 s later, the fish made a binocular saccade coordinated with a slow body turn. After the fast turn, if slow body movements occurred, the eyes seemed to be fixated in space (compare eye position in Fig. 2*a* between the two turns).

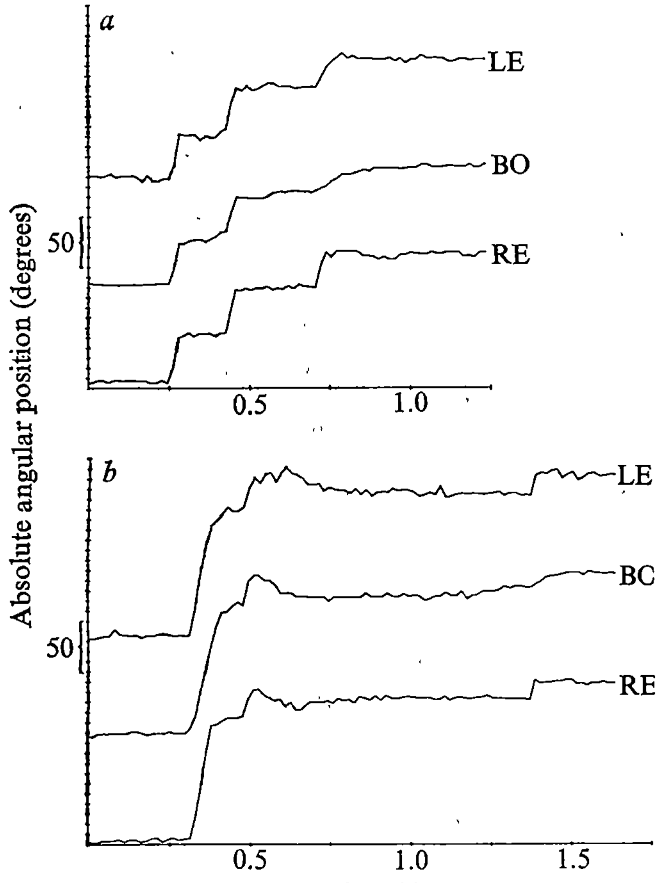


Fig. 2 *a*, Two successive fast body turns followed by a saccadic eye movement (at 0.75 s). During the fast turns there is no eye motion relative to the body. *b*, One large fast turn, followed by a small one and then later (at 1.3 s) a saccadic eye movement.

Both the angular size and angular speed of fast body movements far exceed those of body movements associated with saccadic eye motion (Fig. 3). In fact, the rotational velocity of the body during a fast turn approximates that of the eye during a typical saccadic flick (compare Fig. 2).

Compared with a normal aquarium, the tank I used had a relatively small volume for habitation by several fish, and this artificial crowding intensified the behavioural interaction in response to alteration of the social situation After a fish had been introduced into the tank, there was a short quiescent period of adaptation to the new environment of about 10 min. Some time thereafter, vigorous fighting ensued (threat displays, biting, chasing, mouth-to-mouth biting and pulling), which seemed similar to territorial disputes in larger aquaria. The fighting continued (0.5–1.5 h) until one fish clearly dominated the tank, having won in paired encounters with all contenders. Only rarely was this social order then changed without the addition or removal of fish.

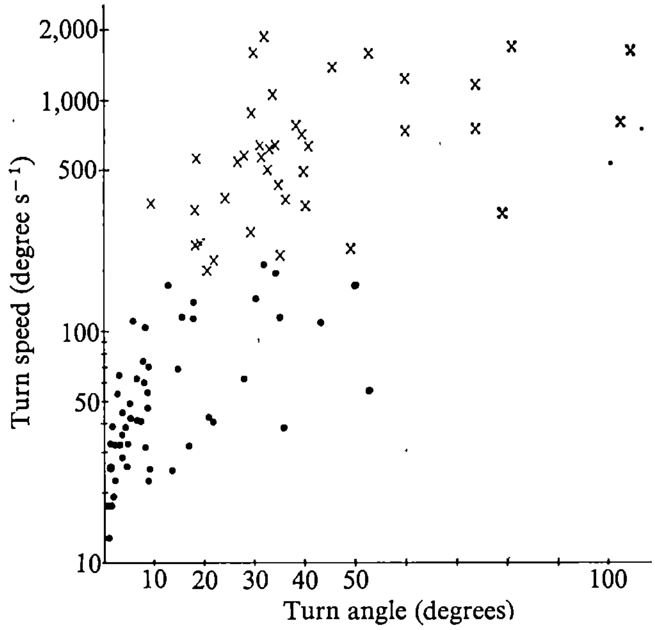

Fig. 3 For body movements, the turn size (degree) is plotted against the turn velocity (degree s^{-1}). Body movements for both fast turn (×, $n = 39$) and saccadic eye movements (●, $n = 52$) are shown.

The fast turns were recorded only during these paired encounters. The animals oriented themselves for subsequent bites, threats and so on with a fast turn just before the behavioural act. The two fast turns in Fig. 2*a*, for example, preceded a vigorous bite into the opponent's tail, after which the attacked animal fled. If the dominant animal was removed from the tank, the remaining fish resumed fighting and performing the corresponding fast turns until a new male dominated.

It is not yet clear whether the fast turn serves as a behavioural signal, intentional or otherwise, in addition to its orienting function. These turns produce a unique sound (Fig. 1 of ref. 3) and can be recognised by a trained observer. The combined auditory and visual information could serve to alert fish nearby.

The fast turns are neither identically long nor large, but seem to be matched to the behavioural situation, which suggests that there is a large coordinated muscular discharge under rather precise control. Two factors make control of this turn unique: first, during the turn, the eyes are fixed with respect to the body, and second, the time spent turning is very short. Both imply that the fish may be making the turns under open loop control, without use of visual or other feedback, a possibility which must be tested experimentally.

I thank Ms N. Hirata and Mr L. Schmuck for help and Drs S. Zack and W. Heiligenberg for helpful comments. This work was supported in part by the Sonderforschungsbereich 50 Kybernetik.

Multicomponent alarm pheromones of the weaver ant

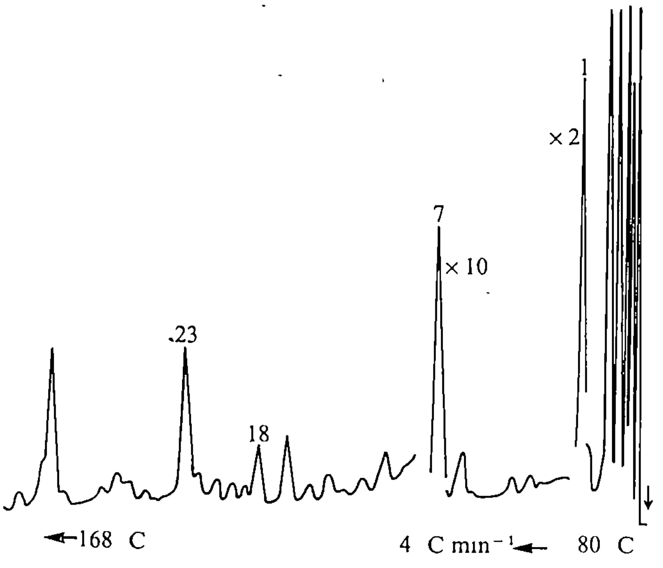
THE exocrine glands of ants are often found to contain blends of volatile chemicals[1], but only rarely have distinct releaser properties been ascribed to different components of a single gland[2–4]. The African weaver ant *Oecophylla longinoda* is notoriously aggressive in defending its territory, and communication of alarm is rapid and efficient. Colony defence is carried out almost exclusively by the major workers, the minor caste remaining within the leaf-nest until this is directly disturbed[5]. This marked difference in behaviour may reflect a biochemical polymorphism, although this has not yet been reported for alarm pheromones of ants[6]. We have therefore initiated a detailed study of exocrine secretions that could be implicated in the control of alarm and defence in this ant. In the mandibular gland we have found over thirty compounds, some of which control separate aspects of behaviour. The mandibular gland contents also differ markedly among castes.

Excited major workers often give out a fragrant but musty odour, which originates from the mandibular glands. Crushed heads or mandibular gland reservoirs release a sequence of behaviour, which may be broken down into four components: alerting, in which the ants raise their heads and open their jaws, and may snap at nest-mates nearby, attraction towards the source of the chemicals, arresting of locomotion at close range, and biting. The last is a particularly marked reaction, in which the ant often pulls for several minutes if resistance is offered by the object being bitten. Prey is normally immobilised by a number of ants pulling from different directions. Gas chromatography of single mandibular glands indicated that at least 33 chemicals are present at or above a level of 5 ng per gland (Fig. 1). The major components were identified as hexanal (1) and 1-hexanol (7). Pure samples of these were presented to laboratory cultures of the ants in capillary tubes, which give a release rate comparable with that produced by the ants[7]. Hexanal releases alerting and alarm with little evidence of directional orientation, while a source of 1-hexanol attracts ants towards it from a radius of about 10 cm, but the ants are alarmed and repelled at a distance of a few mm from the source. The biting behaviour is apparently under the control of less volatile components, since this can be observed in response to the mandibular gland secretion after it has been allowed to evaporate for a few minutes, and no longer releases alarm.

Small quantities of the components eluting after 1-hexanol were collected as broad fractions by solid-sample preparative gas chromatography[8] and were presented to foraging major workers. The fraction containing peaks 18–23 was most active in releasing biting (Wilcoxon matched-pairs signed-ranks test, $T=1$, $N=8$, $P<0.01$, one-tailed test) compared with controls. This fraction was further divided into individual components, and peaks 18 ($T=10$, $N=10$, $P<0.05$) and 23 ($T=0$, $N=7$, $P<0.01$) were most active. They were shown to be 3-undecanone (18) and 2-butyl-2-octenal (23) by mass spectrometry and comparison with commercial (18) and synthetic (23) samples (full details of the structure elucidation will be published elsewhere). The combination of 1-hexanol, hexanal and 2-butyl-2-octenal has also been found in the coreid bug *Amblypelta nitida*[9]; a linked biosynthesis seems likely in both species. 2-Butyl-2-octenal and 3-undecanone were tested in the quantities found in a single gland (50 ng and 20 ng respectively). Both released biting, although the aldehyde was more active than the ketone ($T=14$, $N=12$, $P<0.05$, two-tailed test). The ketone is also an attractant over a 2-cm range.

The behaviour released by the total mandibular gland secretion has been compared with that described for the four chemical stimuli we have isolated (Fig. 2). It seems that a sequential message is produced from the active spaces[10] of these chemicals determined both by their individual volatilities within the mixture and their threshold concentration for the particular response. In still air the spaces will be concentric about the point of deposition of the secretion detailed in Fig. 2. Behavioural tests indicate that hexanal has the most rapidly expanding activity; this is followed by 1-hexanol, which attracts the ants towards the smallest active

Fig. 1 Gas chromatography of the head of a single major worker of *Oecophylla longinoda*; 1.5 m by 6 mm outside diameter glass column packed with 10% polypropylene glycol adipate, the oven held at 80 °C for 5 min, then programmed to 168 °C at 4 °C min^{-1}, injection (arrowed) by solid-sample[11]. Only those components discussed in the text are numbered.



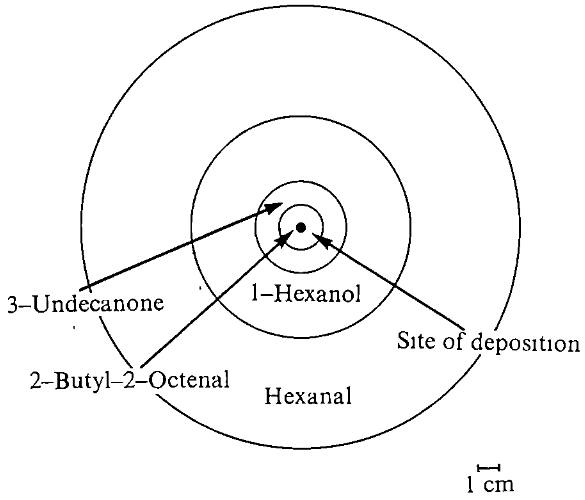


Fig. 2 Active spaces of four mandibular gland components 20 s after deposition. (1) Hexanal and 1-hexanol were presented to foraging workers as pure compounds in glass capillary tubes (1 mm inside diameters) open at one end, which give a release rate comparable with that produced by the ants[7]. After 20 s, the alerting and alarming activity of hexanal extended to a radius of 10 cm, and orientation and running towards a source of 1-hexanol began at a radius of 5 cm. (2) 3-Undecanone and 2-butyl-2-octenal were presented on small flags of filter paper which were first washed in redistilled methylene chloride and were fixed to the foraging table on fine entomological pins. Test solutions of 20 ng of 3-undecanone and 50 ng of 2-butyl-2-octenal (the quantities found in a single mandibular gland of a major worker from the colony under test) were measured on to the filter paper and the solvent (hexane) allowed to evaporate. Control filter papers were treated with solvent only. Over a 20-s period, ants were attracted to 3-undecanone over a 2-cm radius, but biting behaviour in response to either 3-undecanone or 2-butyl-2-octenal was observed only within 1 cm of the pin. Observations on behaviour in response to the total mandibular gland secretion showed that the active spaces of the components were approximately the same in combination as they were when tested individually.

spaces, those of the biting markers. 3-Undecanone may provide an additional directional cue at closer range. The effects of the individual components seem to be additive, rather than synergistic, as observed in two laboratory cultures, collected from the forest areas of Ile-Ife and Ibadan, Nigeria. Pure 3-undecanone released biting in a third culture, collected about 700 km to the north, in savanna at Mokwa, but 2-butyl-2-octenal was inactive alone. A sample containing an equal amount of the aldehyde and 1-hexanol restored the activity to the same level as the ketone: mandibular glands of major workers collected from Mokwa differ in containing 1-octanol and 1-nonanol in addition to 1-hexanol, and these less volatile alcohols may be more persistent synergists. In either case a rapid communication of alarm is achieved, while the attack response is localised to the object on to which the mandibular gland secretion has been deposited.

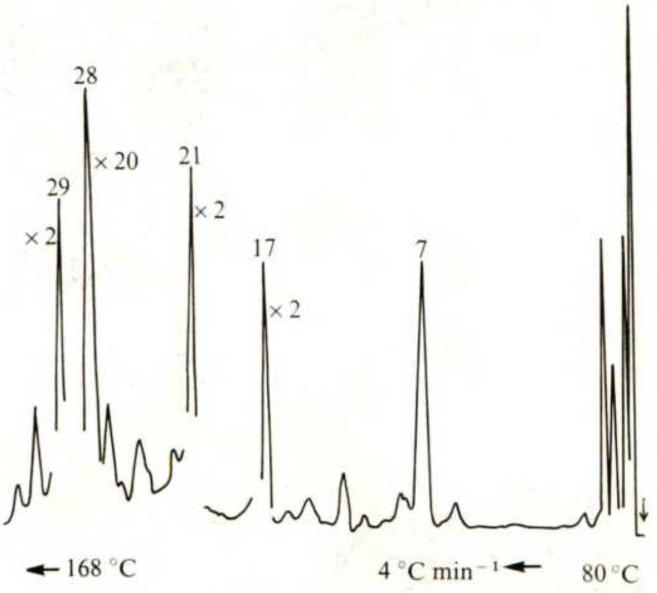

Fig. 3 Gas chromatography of the head of a single minor worker head of *Oecophylla longinoda;* experimental details as for Fig.1, vertical scale increased × 2.

Gas chromatography of single heads of minor workers (Fig.3) indicates considerable differences from majors; the main component (28) was identified as nerol, with geraniol (29), 1-hexanol (7), 1-octanol (17) and 1-nonanol (21) also present. Hexanal, 3-undecanone and 2-butyl-2-octenal seem to be absent at the level detected (~2 ng per ant). Minor workers exposed to either 1-hexanol and nerol in capillary tubes are repelled, and thus displaced from sources of disturbance. Major workers are attracted and arrested at about 1 cm from a source of nerol in a capillary, but this reaction is not observed until about 2 min after the tube is placed on the foraging table, which indicates a high threshold concentration. A disturbance within the confined space of the leaf-nest would result in a rapid and rather uniform increase in the concentration of 1-hexanol, decreasing its effectiveness as an orientation stimulus. For the same release rate, the active space of nerol is smaller and slower to expand, and this could enable excited minor workers to be located by majors.

Two further methods of alarm communication are found in this species. Major workers strike their bodies against the leaf-nest when it is disturbed, the sound being likened by Weber[5] to dry peas dropping on to a plate, and several major workers then appear at the nest entrance. The abdominal defensive secretion also releases alarm behaviour, but only two compounds seem to be involved. A mixture of formic acid, found in the poison gland, and *n*-undecane from the Dufour gland, releases alarm, attraction and attack. The mixture is considerably more effective than either component tested separately. The poison and Dufour gland secretions of major and minor workers are qualitatively similar.

This study has focused on only a few of the many chemicals which may have a role in the control of alarm and defence behaviour in this species, and suggests that the simple concept of an alarm pheromone governing behaviour by virtue of one major component may be inappropriate for ants. It also demonstrates that biochemical polymorphism and population differences exist and should be taken into account in future studies.

Penetration of mid-gut cells of *Glossina morsitans morsitans* by *Trypanosoma brucei rhodesiense*

UNTIL recently, the developmental cycle of African sleeping sickness trypanosomes in tsetse flies (*Glossina* spp.) was thought to follow exclusively the pattern described by Robertson[1]. She suggested that trypanosomes ingested by a fly taking an infected blood meal multiplied in the gut and eventually invaded the salivary glands directly without leaving the confines of the alimentary tract. Inside the salivary glands the trypanosomes could develop into metacyclic forms capable of initiating fresh infections in mammals. In 1972, Mshelbwala[2] described stages of *Trypanosoma brucei* he had found in the haemolymph of three species of tsetse fly, and suggested that a more direct route from the gut to the salivary glands existed. According to his hypothesis, the trypanosomes from the gut of the fly penetrated the gut wall and entered the haemocoel; they then migrated to the salivary glands directly through the haemocoel, penetrating the glands and so completing the cycle of development in the fly. At this time there was no direct evidence that salivarian trypanosomes could penetrate the gut wall of their insect vector. In this communication we present electron microscopic evidence that *T. b. rhodesiense* penetrates the mid-gut cells of *G. morsitans morsitans*.

Tsetse flies are difficult to infect with trypanosomes of the *T. brucei* complex, and one suggested[3] reason for this is failure by the trypanosomes to complete the biochemical and morphological changes by which the bloodstream trypanosomes transform to mid-gut forms. To overcome this difficulty, we cultured *T. b. rhodesiense in vitro*, producing forms which are believed to correspond to mid-gut forms, which were then fed to the flies.

Laboratory-fed *G. m. morsitans* were fed artificially through agar–Parafilm membranes[4] on a diet of defibrinated horse blood containing approximately 2×10^5 culture-form trypanosomes per ml. These culture forms were grown to mid-log phase in a human blood lysate broth medium[5], and were derived from a strain of *T. b. rhodesiense* (180 TS1) isolated by Dr W. E. Ormerod from a human patient in Botswana. The flies which provided material for the electron micrographs presented here were fed on six occasions. The first three feeds

Fig. 2 Transverse section of two invaginated pockets in a gut-cell containing numerous trypanosomes. The membranes of these pockets are clearly seen unlined with microvilli.

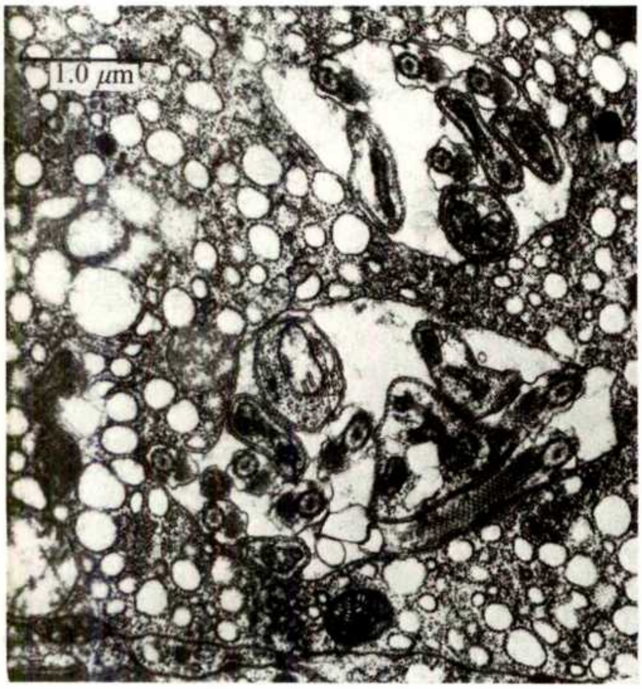

Fig. 4 *a*, Higher magnification of a trypanosome pellicle ▶ (arrowed) showing the parasite within the gut cell and free of any host-cell membrane. *b*, Two trypanosomes lying between the mid-gut basement membrane and the membrane of the haemocoel (arrowed). All sections were stained with lead citrate.

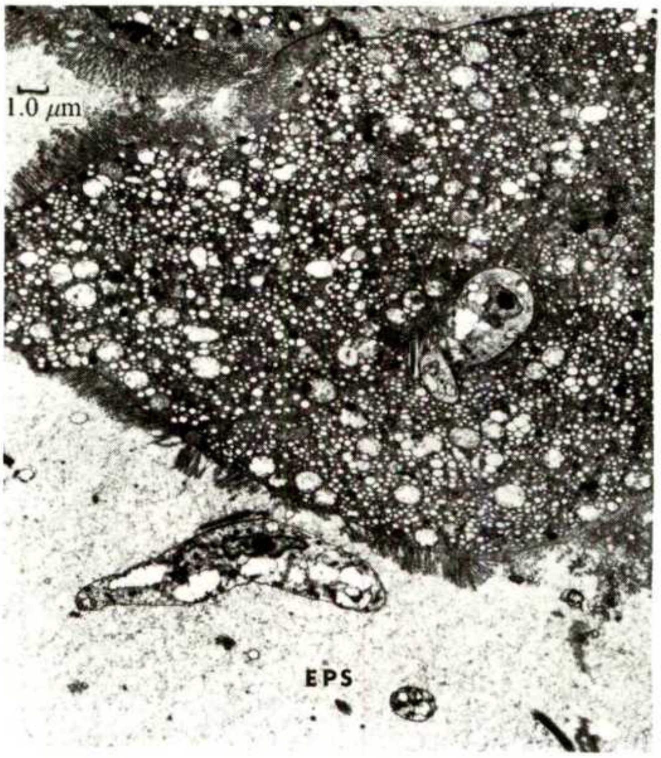

Fig. 3 Two trypanosomes within the cytoplasm of a mid-gut cell. Other trypanosomes are visible in the ecto-peritrophic space (EPS).

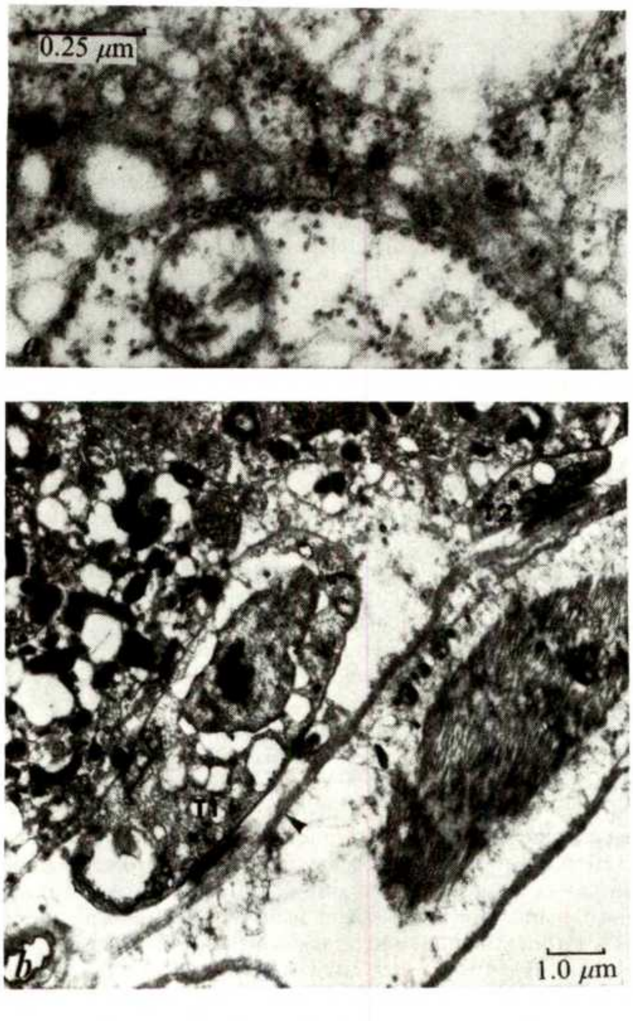

were of trypanosome-infected blood, and the remaining feeds contained defibrinated blood alone. Twenty-one days after their first infected feed, the flies were killed and their guts dissected out. The guts were fixed in 3% (v/v) cacodylate-buffered glutaraldehyde (6 h at 4 °C), washed overnight in cacodylate buffer, postfixed in cacodylate-buffered 1% (w/v) osmium tetroxide and prepared for embedding in Araldite.

The electron micrographs presented here show trypanosomes in the ecto-peritrophic space of the mid-gut, close to the brush border of the gut epithelium, and penetrating, flagellum first, the brush border membrane. This membrane, now surrounding the trypanosome flagellum (Fig. 1), has the appearance, when viewed in transverse section (Fig. 2), of a vacuole within the host cell containing numerous parasites. Once wholly inside the gut cell (Fig. 3), the trypanosomes lie free, no longer surrounded by host cell membrane (Fig. 4*a*).

Finally, the trypanosomes reach the basement membrane of the gut cell, which they penetrate, and come to lie in the space between the gut cell basement membrane and the haemocoel membrane which sheaths the gut (Fig. 4*b*).

It seems that entry of the trypanosomes into tsetse fly mid-gut cells is an active process on the part of the trypanosomes, and not a result of phagocytic action of the mid-gut cells, nor was evidence found of passive enclosure of trypanosomes between gut cells during the extension and contraction following blood meals. This view is supported by our finding that the intracellular parasites are in no way associated with the membranous system of the host cell; the electron microscopic appearance of the intracellular trypanosomes, and the discovery of undamaged parasites in the space between the gut cell basement membrane and the haemocoel membrane, suggest that the trypanosomes are not affected by the gut cells.

A route from the gut of an insect vector through the haemocoel to the salivary glands has been described for other parasitic protozoa. *T.* (*Herpetosoma*) *rangeli* migrates to the salivary glands of its reduviid bug vector in this manner, as do malaria sporozoites in the mosquito. Whether this route is important for sleeping sickness trypanosomes is unknown, but this is being investigated.

T cells mediate transplantation tolerance

SEVERAL cellular mechanisms have been postulated to account for the phenomenon of transplantation tolerance in animals injected at birth with allogeneic or semi-allogeneic cells. These include deletion of the clone of specific alloantigen sensitive cells[1], continuous production of conventional blocking alloantibody[2] or anti-receptor antibody[3] and the action of suppressor cells[4]. Although these phenomena have been demonstrated in tolerant animals, it has never been shown that either alone or in combination they are actually capable of inducing true transplantation tolerance. In the course of experiments designed to prove formally that recirculating small lymphocytes are responsible for first-set rejection of skin grafts, we obtained results suggesting that rapidly recirculating cells from tolerant donors might be capable of actively transferring a state of transplantation tolerance (TT) to irradiated recipients[5,6]. These results, which suggested that the transfer of TT was due to humoral or cellular suppressor mechanisms, were not consistent with the clonal deletion theory of tolerance. The present experiments were designed to confirm that TT is not merely the absence of reactivity to a given set of allo-antigenic determinants but an active suppression of reactivity to those determinants, and to determine whether T or B cells mediate this suppression.

Thoracic duct (TD) lymph contains both T and B cells and members of both these subpopulations continuously recirculate from blood to lymph[7]. Cells mediating allo-immune responses *in vivo* are among the populations which recirculate[5,6]. The lymphoid tissues of rats whose own lymphocyte pools have been virtually eliminated by supralethal (1,000 rad) doses of radiation are still capable of supporting the recirculation from blood to lymph of injected TD lymphocytes. Either syngeneic or allogeneic TD lymphocytes injected intravenously into such rats can be recovered from a thoracic duct fistula uncontaminated by significant numbers of radioresistant host lymphocytes[6]. Because the modal transit time of T lymphocytes through lymph nodes is considerably shorter than that of B cells[8,9], peak recovery of injected T cells occurs before significant numbers of B cells begin to emerge (Fig. 1). Collections of lymph made for the first 24 h after injection yield approximately 20% of the injected T cells and virtually none of the injected B cells. We have examined the capacity of both unfractionated TD lymphocytes from tolerant donors, and pure T-cell populations separated from the former by this method, to mediate TT.

Thoracic duct lymph from 10 DA rats tolerant of PVG alloantigens was collected for the first 24 h after cannulation and the cells were washed twice. Aliquots of 3×10^7 cells were injected intravenously into sublethally (750 rad) irradiated DA rats freshly grafted with PVG and Lew skin. The remainder of the cells (1.25×10^9 per recipient) were injected intravenously into supralethally irradiated DA rats bearing thoracic duct fistulae, and collections of lymph

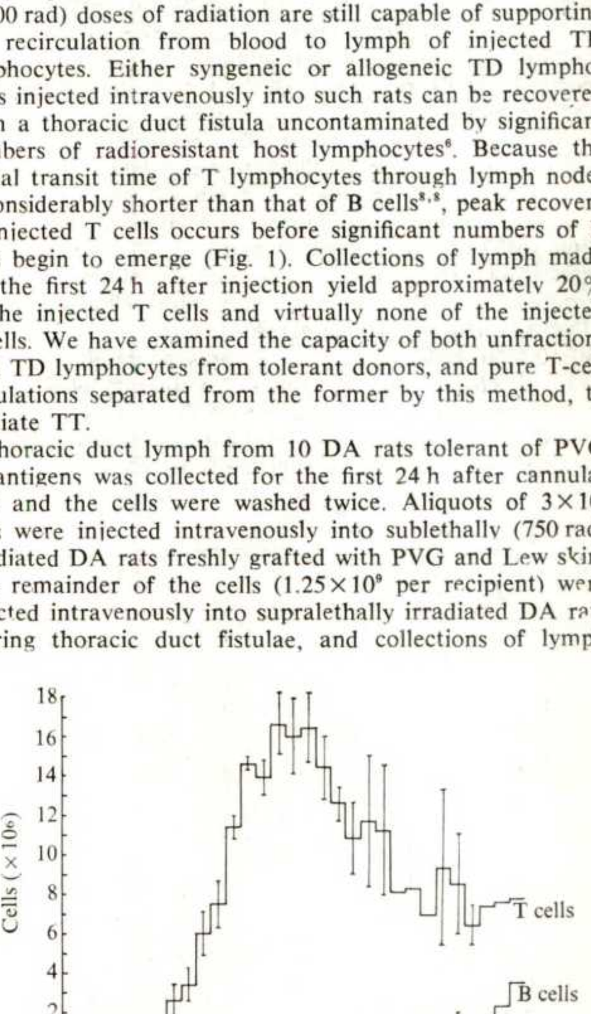

Fig. 1 Output of T and B cells in 1.5-h collections of TD lymph from supralethally irradiated rats (1,000 rad ^{60}Co γ radiation) injected intravenously with 1.25×10^9 syngeneic TD lymphocytes of which 44–48% were Ig positive. All rats were splenectomised at the time of cannulation to prevent temporary sequestration of injected TD lymphocytes in the splenic spool. Cells were counted in each collection and the proportion of Ig-bearing lymphocytes was determined by direct fluorescence using FITC conjugated rabbit antirat Ig serum diluted 1:30 (Burroughs Wellcome, lot No. K7284). T cells were positively identified in representative collections by indirect immunofluorescence using a 1:4 dilution of a rat anti-T-cell serum[15] followed by two washes through foetal calf serum gradients and staining with the same rabbit anti-rat Ig serum as before. Error bars represent the standard errors of the arithmetic means of determinations on eight rats in four separate experiments.

made from these rats for the subsequent 0–22 h and 22–46 h. Cells in each of these collections were pooled and assayed for the proportion of T and B cells. Aliquots of 3×10^7 of these cells were injected intravenously into sublethally irradiated DA rats also bearing both PVG and Lew skin allografts (Fig. 2).

In order to determine the rate of spontaneous recovery of immune responsiveness in rats given 750 rad, groups of irradiated, unrestored rats were doubly grafted in the same way as the experimental groups. In addition, the competence of separated T cells from normal donors to mediate alloimmune responses was confirmed by restoring a further group of irradiated, doubly grafted recipients with 3×10^7 cells from supralethally irradiated DA rats given 1.25×10^9 TD lymphocytes from normal donors. The survival of skin grafts on rats given normal or tolerant T-cell inocula and on rats given no restorative inoculum are presented in Fig. 2. As the behaviour of grafts on rats given unfractionated TD lymphocytes, either normal or tolerant, did not differ from the results obtained with the respective purified T cells, the results of the former are omitted from the life tables for the sake of clarity.

In the unrestored sublethally irradiated control rats, spontaneous recovery of the immune response ensured that both grafts were eventually rejected, although the first-set allograft response was temporarily ablated. Median survival time (MST) for Lew grafts was 17.5 d; the MST for PVG grafts was 25.3 d (Fig. 2, *D* and *E*). When sublethally irradiated recipients were restored with cells from normal donors, whether unfractionated TD lymphocytes containing 40–50% B cells or purified T cells containing less than 0.3% B cells, the rejection times of both grafts were restored to normal (MST Lew, 8.5 d; MST PVG, 9 d) (Fig. 2, *A* and *B*). Previously reported experiments have established that the restored responses in sublethally irradiated grafted rats given TD lymphocytes are mediated by the restorative inoculum[5,6], and that if the clone of cells reactive to PVG antigens is deleted from such a restorative inoculum by filtration through supralethally irradiated PVG rats, the restoration of first-set rejection of PVG skin grafts is specifically abolished; these grafts are rejected with the same MST as in unrestored sublethally irradiated animals[6].

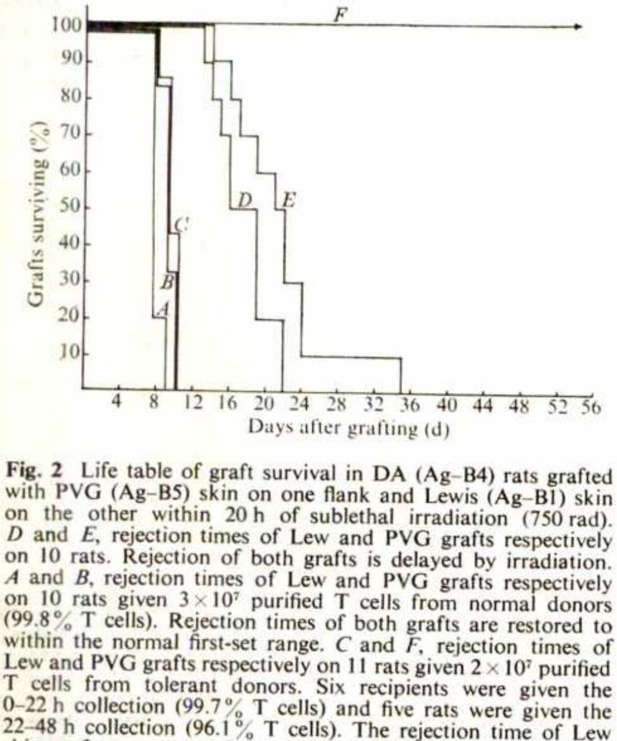

Fig. 2 Life table of graft survival in DA (Ag-B4) rats grafted with PVG (Ag-B5) skin on one flank and Lewis (Ag-B1) skin on the other within 20 h of sublethal irradiation (750 rad). *D* and *E*, rejection times of Lew and PVG grafts respectively on 10 rats. Rejection of both grafts is delayed by irradiation. *A* and *B*, rejection times of Lew and PVG grafts respectively on 10 rats given 3×10^7 purified T cells from normal donors (99.8% T cells). Rejection times of both grafts are restored to within the normal first-set range. *C* and *F*, rejection times of Lew and PVG grafts respectively on 11 rats given 2×10^7 purified T cells from tolerant donors. Six recipients were given the 0–22 h collection (99.7% T cells) and five rats were given the 22–48 h collection (96.1% T cells). The rejection time of Lew skin grafts was restored to within the normal first-set range in both groups. The rejection of PVG skin grafts in both groups was completely suppressed. These grafts are in impeccable condition at the time of writing (> 100 d). Tolerant donors had borne perfect PVG skin grafts for at least 50 d. Pooled TD lymphocytes from these donors were assayed for graft *versus* host activity in $(DA\times PVG)F_1$ and $(DA\times Lew)F_1$ hybrids using the popliteal lymph node assay[16]. Absence of responses in $(DA\times PVG)F_1$ and large responses in $(DA\times Lew)F_1$ confirmed true tolerance in the donors.

The effect of inocula of cells tolerant to PVG antigen in sublethally irradiated recipients was markedly different (Fig. 2). The recovery of reactivity to PVG antigens was not merely delayed, as in unrestored recipients or recipients of clonally deleted cells, but the PVG grafts survived indefinitely in impeccable condition. This phenomenon is not explicable in terms of absence of the clone of alloantigen sensitive cells but implies that populations of tolerant cells contain cells capable of active, specific suppression of the regenerating immune response in animals recovering from radiation.

Both suppressor T cells and specific B-cell products have been implicated as mediators of tolerance in a variety of systems[10]. Tolerant TD lymph contained the same proportion of B cells, 40–50%, as does normal TD lymph. When passaged from blood to lymph in supralethally irradiated rats, 99.7% of the tolerant TD lymphocytes collected within 24 h of injection were T cells. Both this population and later collections (96.1% T cells) were just as efficient as unfractionated, tolerant TD lymphocytes in adoptively transferring specific tolerance (Fig. 2, *C* and *F*). The original donors of tolerant TD lymphocytes had been given 5×10^7 $(DA\times PVG)F_1$ bone marrow cells by intracardiac injection within 24 h of birth and grafted with PVG skin at 12 weeks. The extent of chimaerism in these donors (assessed by dye-exclusion cytotoxicity assays using specific cytotoxic alloantisera of high titre) was below the detection threshold of 5%. This is in agreement with the low levels of chimaerism in tolerant mice reported by other workers using different assay systems[11,12]. Experiments were nevertheless done to exclude the possibility that chimaeric cells in the restorative inocula from tolerant donors could have been responsible for the induction of tolerance in irradiated hosts. The rejection of PVG skin grafts by sublethally irradiated rats was completely unaffected by giving restorative inocula of either 3×10^5 or 3×10^6 $(DA\times PVG)F_1$ cells. The latter would be equivalent to 10% chimaerism. This makes it unlikely that the transfer of chimaeric cells is responsible for the suppressor activity of purified T-cell populations from tolerant donors.

A dose of 750 rad is far in excess of that necessary to abolish completely alloantibody synthesis in rats[13], and restorative inocula containing 20–40 times as many B cells as were present in the restorative inocula used in these experiments will not restore antibody synthesis to such animals[14]. It therefore seems clear that the injected syngeneic T cells alone must have been responsible for the specific suppression which induced tolerance in the irradiated recipients of tolerant T-cell inocula. This result implies that true transplantation tolerance is a positive immune response mediated by T cells which belong to the recirculating pool of small lymphocytes. The origins, life span and mode of action of these cells will obviously be the subjects of further study.

Clonal growth of Hodgkin cells

ALTHOUGH several cell types derived from biopsies of patients with Hodgkin's disease have been grown *in vitro*[1,2], there has been no convincing experimental evidence for the identity and origin of such cells. We wish to present data demonstrating clonal and continuous proliferation of Hodgkin cells, their relationship to Reed–Sternberg cells and their probable origin from B lymphocytes.

Cells were obtained from pleural effusions of two patients with terminal Hodgkin's disease. The lymph node histology at autopsy of both cases was lymphocytic depletion. The cases were selected on the basis of an abundance of Hodgkin and Reed–Sternberg cells in the pleural fluid (Fig. 1): the large Reed–Sternberg cells were binucleate or multinucleate, the nuclei having a coarse nuclear chromatin network and large blue-stained nucleoli. Their cytoplasm was pale and often vacuolated. Cells considered to be Hodgkin cells had the same nuclear and cytoplasmic characteristics, but were mononuclear.

Cells were separated from the pleural effusions by the Ficoll gradient method and cultured in diffusion chambers as described for human bone marrow and peripheral blood cells[3,4]. Figure 2 shows similar growth curves of the cells from both cases during 11 d of culture. An initial decrease in total cell numbers, levelling off on days 2–5, was followed by a steady exponential increase. Net gain of total cells was observed after 8 d in culture in case 2 but not in case 1. During exponential growth, cell doubling times were 48 and 72 h respectively in the two cultures.

After 11 d of culture the cell contents of single diffusion chambers from case 2 were transferred into five to eight new chambers. Subculture was repeated at 11–15 d intervals. This cultured cell line has now been maintained for 4 months with continuous production of cells. Throughout the culture period the proliferative properties of the total population, the morphology of the Hodgkin and Reed–Sternberg cells (Fig. 1) and their proportional distribution (∼30 : 1) remained unchanged.

In both cases the EBNA-test[5] for detection of the Epstein–Barr virus (EBV) genome was negative on the fresh pleural effusion cells.

For chromosome analyses of fresh pleural cells and of cells cultured in diffusion chambers, the direct method was used as before[6]. Contents of three to five diffusion chambers were pooled. G banding was obtained by the trypsin–saline–Giemsa technique[7]. The number of metaphases analysed and the numerical chromosomal data are shown in Table 1. The karyotype of the predominant mode of case 1 was 46,XY,t(3,13),−11,+mar,+mar. One marker chromosome was submetacentric, A_1-sized and had two central bands on the long arms. The other marker was subacrocentric, B-sized and had two proximal bands and one distal band. On day 11 of culture, 8% of the metaphases had 47 chromosomes, the extra chromosome being a No. 21. Otherwise the chromosomal findings of case 1 on days 0 and 11 were very similar, particularly with regard to the translocation and the marker chromosomes which were found in 100% of metaphases. Polyploid metaphases revealed two or three sets of the marker chromosomes. Identity of the translocation chromosome and the marker chromosomes in both preparations was confirmed by their G-banding patterns. The chromosome preparation from a lymph node, removed immediately after death, yielded only one analysable meta-

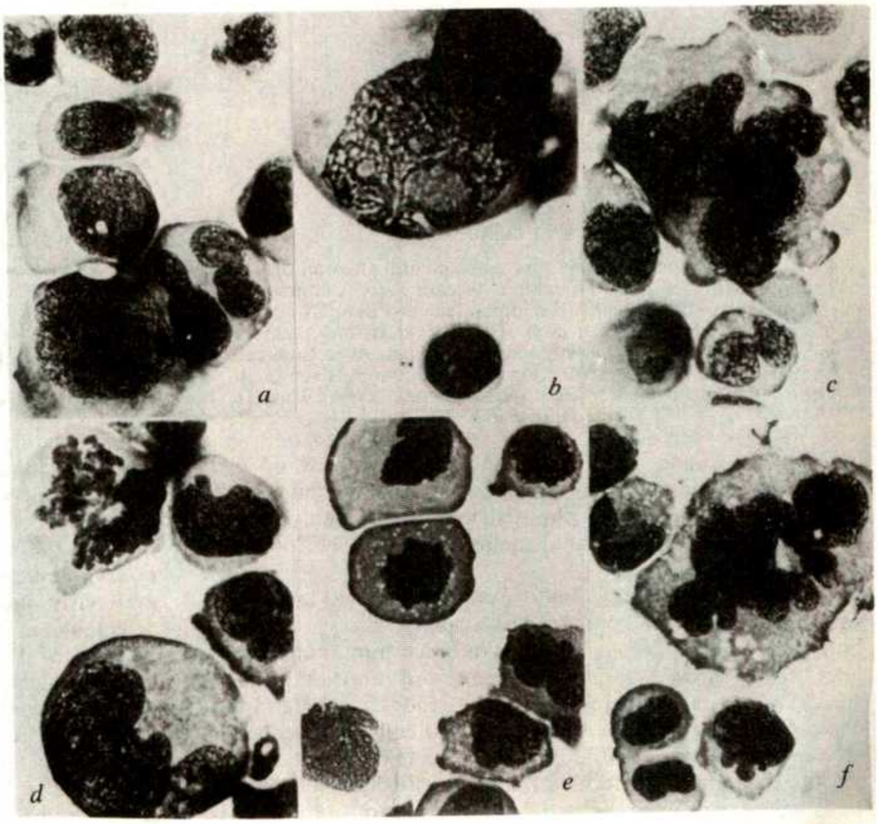

Fig. 1 Composite micrograph showing Hodgkin (HC) and Reed–Sternberg cells (RSC) of case 2. HC and RSC from the original pleural effusion (*a–c*) and after 112 days in diffusion chamber culture (*d–f*). Note normal lymphocyte in comparison to HC (*b*) and mitotic figures of HC (*d–f*). Table 1 Summary of numerical chromosomal findings of cases 1 and 2

	Day 0		Day 11		Day 50	
	Case 1	Case 2	Case 1	Case 2	Case 1	Case 2
No. of metaphases counted	255	100	50	50	0	100
No. of chromosomes per metaphase						
46	86.0%	0	84.0%	0	—	0
47	0	0	8.0%	0	—	0
55–77	4.4%	93.0%	0	100.0%	—	95.0%
82–92	6.6%	0	8.0%	0	—	0
110–130	2.2%	6.0%	0	0	—	4.0%
174–186	0.8%	1.0%	0	0	—	1.0%

phase which, however, clearly demonstrated the translocation and the marker chromosomes described above.

In case 2, G banding revealed up to 17 marker chromosomes in the near triploid metaphases, the origin of most of which remained obscure. The most prominent and consistent among the marker chromosomes were a large submetacentric and two slightly different subacrocentric chromosomes. Some metaphases showed a 1q- and a 6q-. All metaphases had supernumerary chromosomes 19 and one or more missing 13. Karyotypic characteristics of the near triploid metaphases were invariably demonstrable in duplicate or triplicate in the pentaploid or octoploid metaphases. With regard to distribution of chromosome numbers, karyotypic characteristics and banding patterns, the results of chromosome analyses on days 11 and 50 in culture were in agreement with those obtained on day 0.

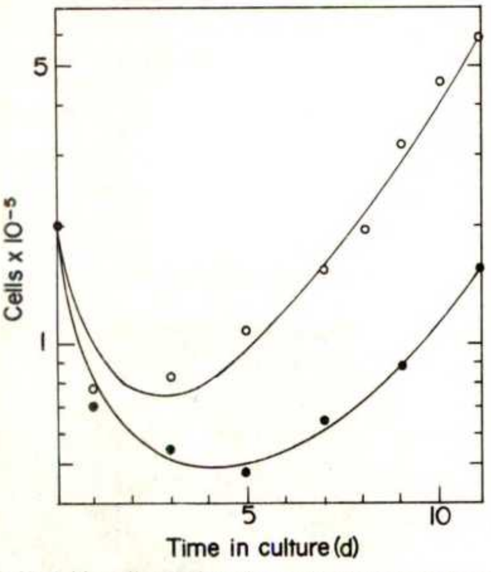

Fig. 2 Hodgkin cells obtained from the pleural effusion of two patients with terminal Hodgkin's disease were cultured in diffusion chambers which were implanted into the peritoneum of irradiated NMRI mice (800 r. ^{60}Co 1 d before chamber implantation), and reimplanted on day 8. Changes in total cell number are shown as a function of time. Symbols represent mean cell number of six to eight diffusion chambers. ●, Case 1; ○, case 2.

On days 0 and 50 the chromosome numbers of 400 further metaphases were estimated at low magnification. The results substantiated the distribution of ploidy values given in Table 1. No normal metaphase could be found at any time in either case.

Cell surface immunoglobulins were determined as before, using an antiserum prepared in rabbits against human immunoglobulins G, A and M[8]. Indirect immunofluorescence tests showed a bright membrane fluorescence in 86% (case 1) and 79% (case 2) of the Hodgkin cells and the Reed–Sternberg cells. We looked at 300 cells of case 1 and 200 cells of case 2. This fluorescence was demonstrated both on the cells directly obtained from the effusions and on the cells collected from the chambers after 50 d of culture. It is thus less likely that immunoglobulins bound secondarily to the cell surface were detected. Spontaneous rosette formation with sheep red blood cells was studied by standard techniques[9]. Neither the Hodgkin nor the Reed–Sternberg cells were positive.

Our findings show that the Hodgkin cells we investigated are capable of continuous monoclonal growth. When cultured in diffusion chambers their growth is exponential, with doubling times of 48–72 h. Chromosome analyses suggest that diploid and triploid Hodgkin cells are precursor cells of the polyploid Reed–Sternberg cells. The demonstration of immunoglobulins on the cell surface even after weeks in culture and the absence of rosette formation point to a B-cell origin of both Hodgkin and Reed–Sternberg cells.

We thank Professor H. zur Hausen, for doing the EBNA-test. This work was supported by grants from Landesamt für Forschung Nordrhein-Westfalen and Deutsche Forschungsgemeinschaft.

Absence of infectious Epstein–Barr virus in blood in acute infectious mononucleosis

CULTURES of peripheral leukocytes from patients with infectious mononucleosis (IM) readily give rise to B lymphoblastoid cell lines containing Epstein–Barr virus genome. Recent experiments have shown that such lines arise not through the direct outgrowth of cells infected by EB virus *in vivo* but as a result of the transformation *in vitro* of previously uninfected B lymphocytes by infectious virus detectable in the cultures at an early stage[1,2]. For in cocultures of IM leukocytes and an equal number of foetal leukocytes, the cell lines which emerged were exclusively of foetal origin in 6 out of 16 cases and of mixed origin with foetal cells frequently predominating in the remaining 10 cases; yet foetal cells cultured alone never gave rise to lines[1]. More important, the inclusion of neutralising antiserum to EB virus in the medium inhibited the establishment of cell lines both in cocultures of IM and foetal cells and in cultures of IM cells alone[1,2].

The source of the infectious virus was not established absolutely, and one obvious possibility was that it had come directly from the blood of the acute IM patients where infectious particles could already have been circulating either free in the plasma or sequestered in leukocytes. The present experiments argue against this and support the idea that infectious virus originates from a small number of peripheral IM lymphocytes which carry the EB viral genome in a non-infectious form *in vivo* but which are activated to a cycle of virus production *in vitro*.

Heparinised blood samples (30 to 60 ml) were taken from seven patients with acute heterophile antibody-positive IM between 1 and 4 weeks after the onset of clinical symptoms; serum samples were taken at the same time to investigate the EB viral antibody status of each patient as regards neutralising activity[1], anti-viral capsid antigen (VCA) titre[3], and anti-nuclear antigen (EBNA) titre[4].

About 5 ml of each blood sample was immediately centrifuged at 1,000*g* for 10 min and the supernatant plasma was rapidly frozen, and stored at −70 °C. The remaining blood was centrifuged on Ficoll–isopaque, and the mononuclear cells were collected and washed as previously described[1], and then divided into three samples for the following treatments: (1) Some washed mononuclear cells were suspended in medium (Eagle's minimum essential with 15% foetal calf serum), cultured in plastic vials at a concentration of 2×10^6 to 3×10^6 cells ml^{-1} and observed regularly for 8 weeks for evidence of transformation, as in earlier work[1]. (2) Half the remaining washed mononuclear cells were used to prepare an extract (day 0 extract); the cells were suspended in the medium at a concentration of 1.5×10^8 to 2×10^8 ml^{-1}, disrupted by three cycles of rapid freezing and thawing, and centrifuged at 5,000*g* for 20 min to deposit the debris, after which the supernatant was collected and stored at −70 °C. (3) The rest of the washed cells were cultured for 3 d and were then similarly extracted (day 3 extract) in an equal volume of medium to that used on day 0.

Table 1 Incidence of transformation in cultures of foetal leukocytes exposed to plasma and to extracts of mononuclear cells from acute IM patients

Patient no.	Plasma preincubated with EB virus negative serum	Plasma preincubated with Antiserum to EB virus	Day 0 extract preincubated with EB virus negative serum	Day 0 extract preincubated with Antiserum to EB virus	Day 3 extract preincubated with EB virus negative serum	Day 3 extract preincubated with Antiserum to EB virus
IM71	0/8	0/8	0/8	0/8	1/8	0/8
IM72	0/8	0/8	0/8	0/8	2/8	0/8
IM74	0/8	0/8	0/8	0/8	6/8	0/8
IM76	0/8	0/8	0/8	0/8	0/8	0/8
IM92	0/8	0/8	0/8	0/8	2/8	0/8
IM94	0/8	0/8	0/8	0/8	0/8	0/8
IM96	0/8	0/8	0/8	0/8	3/8	0/8

The plasma and the two cell extracts from each patient were assessed for their ability to transform foetal leukocytes in culture. Samples of each preparation were incubated for 60 min at 37 °C with either antiserum to EB virus of known neutralising activity or negative serum; the mixtures were then shaken with fresh foetal cord blood leukocytes for 60 min after which the foetal cells were washed, set up in microtestplate cultures, and observed for 8 weeks for evidence of transformation. The techniques used have already been described[1].

The incidence of transformation of the foetal leukocytes after exposure to the various preparations is shown in Table 1. No transformation occurred in any culture of foetal cells exposed to IM plasma or extracts of fresh IM mononuclear cells (day 0 extracts). In contrast, five out of seven IM mononuclear cell extracts prepared after 3 d of culture (day 3 extracts) showed detectable leukocyte-transforming ability; this ability obviously depended on the presence of infectious EB virus since it was only manifest with those extracts pretreated with negative serum and was abolished by pretreatment with neutralising antiserum to the virus. Confirmation of the role of EB virus in the transformation was provided by the finding of EBNA[5] expression in the transformed cells.

Table 2 shows the incidence of, and mean time to, transformation in the cultures of washed mononuclear cells from each patient. It is of interest that those mononuclear cell populations which showed the highest and earliest incidence of transformation when cultured on their own (Table 2) were just those which produced infectious EB virus in culture by the time they were extracted on day 3 (Table 1); conversely the two mononuclear cell samples whose day 3 extracts lacked detectable transforming ability also showed the lowest incidence of transformation when cultured alone.

This correlation confirms and extends similar observations in earlier experiments[1]. Table 2 also shows that by the time the patients were investigated in the present study all seven had developed low, but detectable, neutralising antibodies to EB virus, seven had antibodies to VCA, and two had low anti-EBNA titres, but there is no obvious relationship between the serological status of the patients and the behaviour of their mononuclear cells in culture. Nevertheless, the range of serological findings among these seven IM patients is in agreement with results from larger studies[4,6].

Thus, the present experiments show that IM patients with clinically manifest disease do not have infectious EB virus in the circulation. At this stage infectious virus is not sequestered in some protected site within peripheral lympho-

Table 2 Acute IM patients: transformation in mononuclear cell cultures and anti-EB virus titres in sera

Patient no.	Transformation Incidence	Transformation Mean time (weeks)	Serum titre Neutralising	Serum titre Anti-VCA	Serum titre Anti-EBNA
IM 71	4/6	4.5	1:10	1:80	1:10
IM 72	6/6	3.3	1:5	1:80	< 1:2
IM 74	4/6	3.5	1:5	1:80	< 1:2
IM 76	0/6	—	1:20	1:160	< 1:2
IM 92	6/6	4.2	1:20	1:320	1:10

IM 96	6/6	2.8	1:5	1:80	< 1:2

cytes nor is it present as a viraemia, although the latter must obviously occur during prodromal phases before neutralising antibodies develop.

It seems clear therefore that the origin of the EB virus particles present early in cultures of IM mononuclear cells (Table 1, day 3 extracts and ref. 1) and responsible for their transformation to give cell lines, must be peripheral lymphocytes carrying the viral genome in a non-infectious form *in vivo*. These cells when placed *in vitro* do not have the inherent capacity to grow directly into lymphoblastoid lines but are activated into a cycle of virus production; it is this virus which is crucial for the initiation of cell lines since the whole process is inhibited in the presence of neutralising antiserum[1,2]. Peripheral cells in IM must therefore carry EB virus in a different form of infection from that of the malignant cells in Burkitt's lymphoma, where the presence of the viral genome is associated with a ready ability to grow out directly *in vitro* to give a lymphoma cell line[7-9].

It has been suggested[10] that the type of EB viral infection shown by circulating cells in IM may be closer to the latent infections established in ganglia by herpes simplex[11] and varicella-zoster[12] viruses, where the viral genome can remain apparently unexpressed for long periods but can be activated into a cycle of virus production by a variety of stimuli including placing the ganglia in culture[13].

The presence of infectious EB virus in the throat washings of infected individuals[14,15] (whether primary infection was not apparent, or associated with IM) shows that there is a site of virus replication within the oropharynx. It may be that virus-infected lymphocytes leaving this site and entering the circulation have their productive cycle of virus replication repressed in some as yet unexplained way by the combined actions of the cell-mediated and humoral immune responses which are mounted against EB virus-related antigens. Cells containing EB virus genome, scattered through the body's lymphoid tissues *in vivo* and capable of activation to a virus-productive cycle *in vitro*, would explain why lymphoblastoid lines, closely resembling those produced by the *in vitro* transformation of foetal cells but quite distinct from those of Burkitt lymphoma origin[16,17], are obtainable when lymphocytes are cultured from any lymphoma-free individual who is seropositive for EB virus[18].

Temporary presence of self-reactive cytotoxic T lymphocytes during murine lymphocytic choriomeningitis

MICE injected with lymphocytic choriomeningitis (LCM) virus generate specifically sensitised thymus-derived (T) lymphocytes[1-3]. Such cells have been shown[1,2,4] in *in vitro* ^{51}Cr-release assays to be cytotoxic to target cells infected with LCM virus. The specificity of the cytotoxic reaction has been inferred by the observation that the cytotoxic T lymphocytes (CTL) do not lyse noninfected target cells. Moreover, there is evidence that the activity of the CTLs generated is restricted to those virus infected target cells which are compatible with the CTLs in regard to the major histocompatibility complex (MHC)[5]. This peculiar restriction prompted us to study the specificity of CTLs generated in murine LCM. We observed that 4–6 d after infection with the LCM virus the CTLs generated are specifically cytotoxic to syngeneic target cells, irrespective of whether or not they are infected with LCM virus. On the other hand, as the infection proceeds in time, T-cell mediated cytotoxicity is increasingly restricted to virus-infected syngeneic cells. The results imply that during the early phase after infection, murine LCM may represent an autoimmune phenomenon.

We used strain WE-3 (ref. 6) of the LCM virus. The immunisation regime, the preparation of cells, the characteristics of the cells mediating cytotoxicity and the ^{51}Cr-cytotoxicity assay

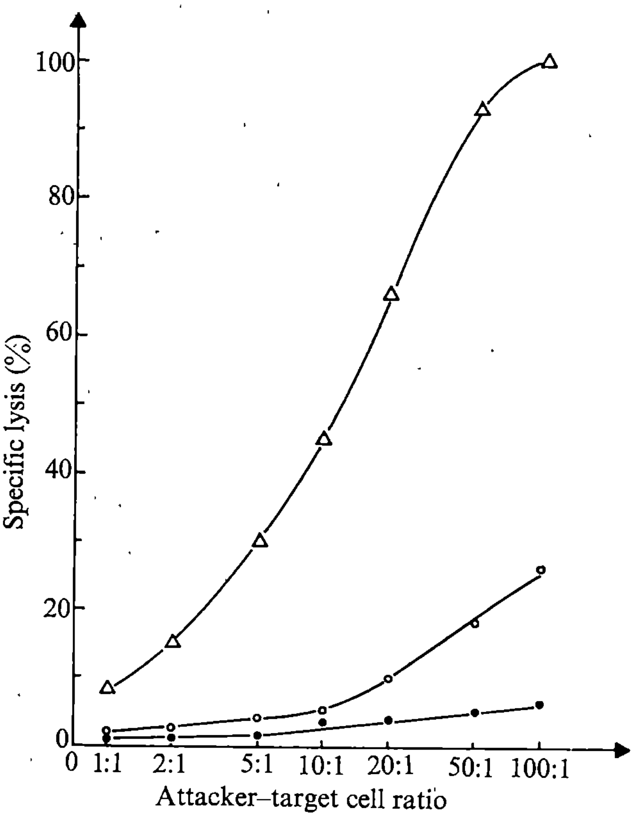

Fig. 1 Dose–response relationship between specific lysis (%) and the ratio of attacker cells to target cells. Spleen cells from LCM infected CBA mice were used at day 8 and tested for cytotoxicity as described in legend to Fig. 2. △——△, Infected L–929 fibroblasts (H–2^k), ○——○, non-infected L–929 fibroblasts (H–2^k); ●——●, non-infected BALB/c embryonal fibroblasts (H–2^d). The spontaneous release of target cells ranged from 20 to 30%. Each point represents the mean of specific lysis (%) obtained at the indicated ratio of attacker cells to target cells. Since in all assays the standard deviation (s.d.) was less than 6%, only the mean is given.

Table 1 Presence of 'self-reactive' CTLs 6 d after infection of CBA mice with LCM virus

	H–2 compatible target cells			Specific lysis (%)	H–2 incompatible target cells

159			58	73		C57BL/6	23
193			89	43			
159	Embryonal fibroblast	CBA	54	50			
163			52	32		C57BL/6	4
167			57	31		BALB/c	14
158	Macrophage	CBA	17	16	Macrophage	C57BL/6	0
142		B10.A	56	29		BALB/c	5

The cytotoxicity of CBA mice was tested at day 6 after intraperitoneal injection of 1,000 LD_{50} of LCM virus. Each value represents the mean of triplicate determinations obtained at an attacker: target cell ratio of 20:1 (18 h ^{51}Cr-release assay). Standard deviation of the data given was less than 6% Spontaneous ^{51}Cr-release ranged from 18 to 25% for L 929 cells, and from 20 to 35% for fibroblasts and macrophages.

have been described by Pfizenmaier *et al*[7]. In brief, virus-infected or normal target cells (peritoneal macrophages, embryonal fibroblasts or L 929 cells) were labelled with ^{51}Cr-chromate and incubated with immune or normal spleen cells for 18 h. The cytotoxicity assays were performed in triplicates. For each cytotoxic lymphocyte population to be tested, a dose–response curve (Fig 1) was produced. The percentage specific lysis was calculated as described by Wagner[8]. That the detected cytotoxicity was mediated by T lymphocytes is indicated by the fact that pretreatment of the cells with anti-Thy 1.2 serum plus complement abolished their cytotoxic activity.

Splenic T lymphocytes of CBA mice infected intraperitoneally with 1,000 LD_{50} LCM virus of the strain WE-3, developed cytotoxic activity against virus infected H–2 identical fibroblast detectable *in vitro* 4–16 d later. Maximal cytotoxicity was detected at day 7–8. H–2 different (allogeneic) target cells were not lysed (Fig. 2). At the peak of the response (8 d after infection) (Fig. 1), the cytotoxic activity generated seems to have been restricted to virus infected target cells compatible with the attacker cells on either the H–2K or H–2D subregion of the MHC. Virus infected target cells compatible on the I-region of the MHC were not lysed (Table 2). The results are in agreement with the work of Doherty and Zinkernagel[9] and suggest that the target for CTL (as generated at day 8 of LCM) is either closely linked to the phenotypical products coded by the H–2K or H–2D subregion of the MHC, or alternatively, represents serologically defined (SD) 'self' antigens which have been altered in the course of the virus infection[5].

Figure 1 demonstrates that the CTLs generated (at day 8 after infection) are also cytotoxic, albeit much less effectively against non-virus infected H–2 identical target cells. Although this finding was first explained by invoking cross reactivity of the target cells, we studied the specificity of the CTLs in more detail. Surprisingly, we found that CTLs generated during the early phase of LCM were unable to discriminate between virus infected and non-infected H–2 identical target cells; that is, both cell types were lysed equally well (Fig. 2). Yet allogeneic, H–2 incompatible target cells were not lysed above the usual background. Moreover, the existence of 'self-reactive' CTLs seemed to be transient and restricted to the first 3 d of the development of cytotoxic activity. In addition, the data given in Table 1 clearly demonstrate that during the early phase of the LCM disease, the generated CTLs lysed not only the syngeneic L cells which were not infected, but also non-infected syngeneic fibroblasts and macrophages. The results therefore suggested, that the 'self-reactivity' can be detected both with L cells, syngeneic fibroblasts and syngeneic macrophages.

On the other hand, the CTLs obtained at the peak of the

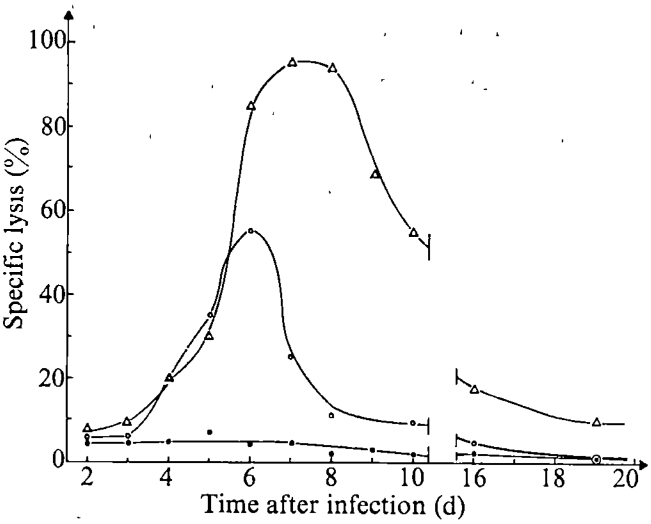

Fig. 2 Kinetics and specificity of cytotoxic T lymphocytes generated during murine LCM. CBA mice were infected intraperitoneally with 1,000 LD_{50} LCM strain WE-3 and at the given time intervals, spleen cells from 3 mice were pooled and tested at different ratios with 5×10^4 target cells in an 18 h ^{51}Cr-release test. Each point represents the mean of specific lysis (%) obtained in triplicate determinations at a ratio of 20 attacker cells to one target cell. Since in all assays the standard deviation (s d.) was less than 6%, only the mean is given. Similar results were obtained in 3 independent experiments. △——△, Infected L-929 fibroblasts (H–2^k); ○——○, non-infected L-929 fibroblasts (H–2^k); ●——●, non-infected BALB/c embryonal fibroblasts (H–2^d). Spontaneous release ranged from 20 to 30%.

Table 2 Specificity of CTLs generated during LCM (8 d after infection)

*3 mice per group were infected intraperitoneally with 1,000 LD_{50} of LCM virus strain WE-3. After 8 d the spleen cells were tested for cytotoxicity in an 18 h ^{51}Cr-release assay. The results given represent the mean specific lysis (%) obtained in triplicate determinations at a ratio of 20 attacker cells to one target cell. The standard deviation (s.d.) was less than 6%. Lysis of non-infected cells ranged from 3 to 10%. Spontaneous release ranged from 31 to 36%.

†Indicates the haplotype of the MHC, that is, the H–2K, IA, IB, IC, and H–2D subregion, respectively.

‡ND, Not done.

response (day 7–8) were found to be maximally cytotoxic for H–2 identical target cells infected by the virus. At that point in time a very limited amount of anti-'self' cytotoxic reactivity was detected in the spleen of infected mice (Figs 1 and 2). That the cells mediating the anti-'self' cytotoxicity during the early stage of LCM were T cells in type was suggested by the fact that their cytotoxic activity was abolished after treatment with anti-Thy 1.2 serum plus complement (K.P., unpublished).

In conclusion, on the basis of the specificity of the generated CTLs two phases may be distinguished during murine LCM. On the one hand there is an early phase, characterised by the existence of both anti-self-reactive CTLs and by cytotoxic activity against virus-infected, H–2 identical target cells. On the other hand, at the time of maximal cytotoxicity (7–8 d after infection) the CTLs generated exhibit cytotoxic activity restricted against virus-infected, H–2 identical target cells. In control experiments we tested whether the lysis obtained in the case of non-infected target cells was attributable to an LCM-virus infection of the target cells by virus released from the effector cell population. Since, however, addition of LCM-virus to a mixture of effector cells (obtained at day 8) and non-infected syngeneic target cells did not result in lysis of the target cells during the 18 h assay time (K.P., unpublished) that possibility seems to be ruled out. Whether the CTLs generated during the early stage of LCM can be separated into those reactive against virus-infected, H–2 identical cells, and those reactive against self antigens or, alternatively, whether the development of a more stringent restriction of the cytotoxic activity reflects a maturation of the CTLs to be generated, is under investigation.

Without the advice and encouragement given by Dr Lehmann-Grube, H. Pette Institute, Hamburg (who provided the LCM virus) and his colleagues, the start of this project would not have been possible. The technical assistance of L. Ptschelinzew and J. Lavaud is acknowledged. This work was supported by the Deutsche Forschungsgemeinschaft.

Evidence against a dimeric structure for membrane-bound HLA antigens

HUMAN histocompatibility (HLA) antigens are expressed on the surfaces of almost all cell types and according to various criteria are integral membrane glycoproteins[1]. They are composed of equimolar amounts of two dissimilar polypeptide chains which are non-covalently linked and which have molecular weights of about 43,000 and 12,000 as judged by polyacrylamide gel electrophoresis in sodium dodecyl sulphate (SDS)[2–4]. The larger chain carries the polymorphic allogeneic specificities and all of the carbohydrate[2]. The smaller chain represents β_2-microglobulin, whose amino acid sequence shows marked homology to the C_H3-domain of the γ-1 chain of immunoglobulin G (ref. 5). This homology and other arguments have led to the proposals that HLA antigens and immunoglobulins have a common evolutionary origin[6,7], and that HLA antigens have an immunoglobulin-like structure in which two basic units of one each of the larger and smaller polypeptide chains are linked either non-covalently[8] or by a disulphide bridge[9,10] to give a 4-chain dimer of molecular weight 110,000. In contrast to the latter proposal, some results presented here suggest that HLA antigens do not have a dimeric structure.

HLA activities were measured by inhibition of cytotoxicity[11] using peripheral blood lymphocytes with sera 3002X, P2692B and P3812B for HLA–A2, sera 1209F, 1014I and P1595B for HLA–A1, sera P1422B and P1538B for HLA–B8, and sera P1040B and P3428B for HLA–B13. A highly purified preparation of the plasma membrane of the lymphoblastoid cell-line BRI 8 (HLA type: A1, A2, B8, B13, 4a and 4b) (ref. 1), and of the plasma membrane fraction of a human spleen prepared by a modification of a method described previously[12] (HLA type: A2, A3, BW35) were used as sources of the whole HLA antigens. More than 86% of the plasma membrane HLA activity were solubilised by 1% Na deoxycholate (pH 8.2) as judged after centrifuging at 100,000g for 1 h.

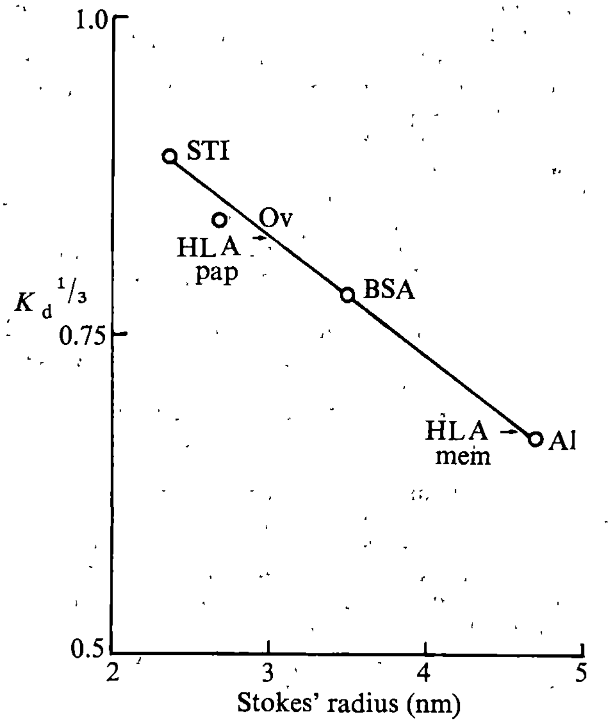

Fig. 1 Relationship between Stokes radii and elution positions ($K_d^{1/3}$) of water-soluble globular proteins from a column of Ultragel AcA 34 in 0.5% sodium deoxycholate. $K_d^{1/3}$ was calculated as previously described[13]. The Stokes radii were those reported by Andrews[14] except for that of soybean trypsin inhibitor which was calculated from the diffusion coefficient and molecular weight[15]. Al, aldolase; BSA, bovine serum albumin; Ov, ovalbumin; STI, soybean trypsin inhibitor. The arrows indicate the measured $K_d^{1/3}$ for the whole HLA antigens (mem) and for the papain-solubilised HLA antigens (pap). Experimental details are given in the legend to Fig. 2.

The molecular nature of HLA antigens was adduced from their gel-filtration behaviour and measurements of their $S_{20,w}$ (ref. 1) and Stokes radii (Fig. 1) in the presence of sodium deoxycholate. Gel filtration of the deoxycholate-solubilised BRI 8 plasma membrane on a column of Ultragel AcA 34 gave (Fig. 2) a single peak of HLA–A2 activity. HLA activities A1, B8 and B13 of the BRI 8 plasma membrane and the HLA antigens of the plasma membrane fraction from the human spleen occupied identical positions with that shown for HLA–A2. Similar elution patterns were also obtained using Sephadex G-150 and G-200, and Sepharose 6B. In each case, the eluted peak accounted for > 86% of the HLA activity added to the column, and no larger aggregates or gross polydispersity was detected. The absence of aggregates in our experiments is in marked contrast with a recent report[10] on a

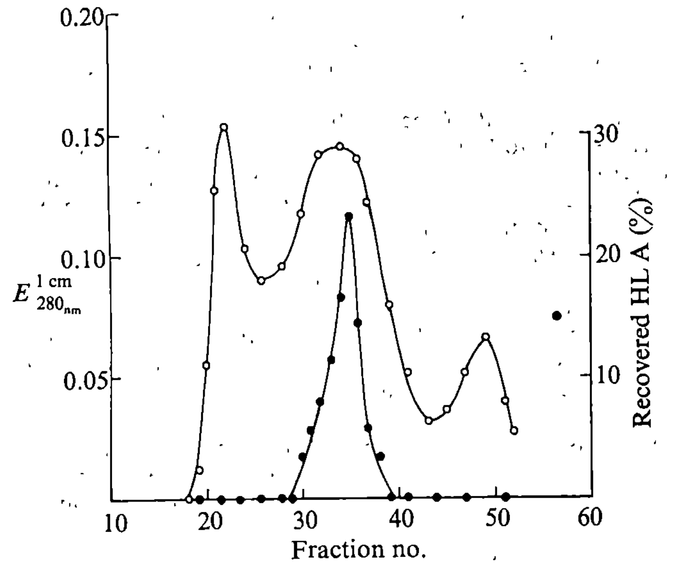

Fig. 2 Gel filtration of deoxycholate-solubilised BRI 8 plasma membrane on Ultragel AcA 34. BRI 8 plasma membrane containing 4 mg of protein was incubated for 30 min at room temperature with 1 ml of 1% sodium deoxycholate in 10 mM Tris-HCl buffer (*p*H 8.2) and centrifuged at 100,000*g* for 1 h. The supernatant (90% of the protein, 86% of the HLA activity) was eluted from a column (91 × 1.6 cm) of Ultragel AcA 34 (LKB Instruments Ltd) with 0.5% sodium deoxycholate at a flow rate of 4.9 ml h^{-1}. Fractions (2.45 ml) were assayed for protein (○; E^{1cm}_{280nm}) and HLA–A2 activity (●). HLA activities A1, B8 and B13 occupied an identical position with that illustrated for HLA–A2. The HLA antigens of the deoxycholate-solubilised plasma membrane from human spleen gave the same elution pattern.

crude membrane preparation from a lymphoblastoid cell line. In that experiment about 40% of the HLA activity was eluted in a second peak, which was provisionally identified as dimer, as well as some larger multimers (see Fig. 3 in ref. 10). The reason for this difference is not known. It is, however, unlikely to be due merely to the use of different cell lines since no aggregates were detected in the current study with human spleen. The main differences between the two studies concern the state of the cells used for membrane preparation and the quality of the membrane fraction. In the present experiments the cells were used immediately after growth (viability > 80%) and the plasma membrane was extensively purified to separate it from endoplasmic reticulum[1]. Furthermore, the HLA antigens were not knowingly subjected to reducing conditions during cell breakage and processing of the plasma membrane. It is possible that Cresswell and Dawson's elution pattern[10] reflects aggregation through disulphide interchange. This aggregation is promoted by storage (compare the elution pattern of an aged sample of human serum albumin[16]). Also, the crude membrane preparations used probably contained endoplasmic reticulum which is rich in an enzyme catalysing sulphydryl–disulphide interchange in various proteins[17].

The molecular sizes and shapes of the HLA antigens in sodium deoxycholate are summarised in Table 1. The values are notable for various reasons. First, the molecular weights of the papain-solubilised HLA antigens in deoxycholate (46,000) agreed closely with those calculated from the values for the β_2-microglobulin and HLA polypeptide chains measured by SDS–polyacrylamide gel electrophoresis (about 12,000 and 34,000, respectively[9]).

Second, the molecular weights of the deoxycholate-solubilised A and B series antigens (88,000 and 78,000 respectively) were larger than those predicted from the sizes of the β_2-microglobulin and HLA polypeptide chains determined by SDS–polyacrylamide gel electrophoresis (about 55,000 including β_2-microglobulin[9]), but were not sufficiently large to accommodate a disulphide-linked dimer. The most likely explanation for this difference is that, as suggested previously[1], HLA antigens resemble other integral membrane proteins (for example cytochrome b_5; ref. 18) in possessing a hydrophobic domain which binds non-ionic and weakly anionic detergents[19,20]. As a result the deoxycholate-solubilised HLA antigens will possess anomalously high molecular weights when assessed relative to water-soluble globular proteins. This anomaly will not, however, apply to estimates of the molecular sizes of the papain-solubilised antigens, because of the removal of the hydrophobic domain during proteolysis and the consequent loss of detergent binding. If it is assumed that the true molecular weight of HLA antigens is 55,000 (as determined by polyacrylamide gel electrophoresis[9]) and that the difference between this molecular weight and those reported for the whole antigens in Table 1 is entirely due to bound detergent, then the A and B series antigens bind 0.57 and 0.39 g of deoxycholate per g of protein respectively. These values are in accord with those reported for various membrane proteins (0.29–0.64 g per g of protein)[20] and with those estimated by equilibrium dialysis for two fractions of BRI 8 plasma membrane containing about 3 and 15% of HLA antigens (0.68–0.72 g per g of protein; D. Snary, unpublished). Detergent binding is also consistent with the higher molecular weights reported for HLA and H–2 antigens (460,000 and 380,000, respectively) in different non-ionic detergents (Brij 99 and Nonidet P40 respectively)[3,21], since these probably express the higher micelle sizes of the bound detergent.

Alternatively, the larger molecular weight of the deoxycholate-solubilised HLA antigens could accommodate a non-covalently bonded dimer[8] if deoxycholate caused dissociation. This is considered improbable primarily because comparisons of the gel-filtration patterns of haemoglobin on Sephadex G-200 in the presence and absence of 1% Na deoxycholate failed to reveal any evidence for dissociation. This result is especially significant since haemoglobin is already partly dissociated in aqueous solution and the majority of the interactions between the α_1 and β_2 subunits are non-polar[22] and would be expected to be particularly sensitive to dissociation by detergent.

Third, the apparent difference between the molecular weights of the deoxycholate-solubilised A and B series antigens (Table 1) probably arises from a larger amount of deoxycholate binding to the A antigens than to the B antigens. This variation may reflect a difference in hydrophobicity in which case it may indicate that the A series antigens are inserted more deeply into the lipid bilayer than B series antigens.

Fourth, estimates of the frictional ratios[13] of the A and B antigens gave 1.49 and 1.55 respectively. Although these values suggest that the membrane-bound antigens are moderately

Table 1 Molecular size and shape of HLA antigens in sodium deoxycholate

HLA antigens	Antigen series	$S_{20,w}$	Stokes radius (nm)	Molecular weight	f/f_0
Na deoxycholate-solubilised	A	5.15	44.0	88,000	1.49
	B	4.55	44.0	78,000	1.55
Papain-solubilised	A, B	3.68	29.8	46,000	1.26

$S_{20,w}$ values were determined previously by sucrose density gradient centrifugation in 1% sodium deoxycholate (see Table 3 in ref. 1). The Stokes radii were measured by gel filtration on a column of Ultragel AcA 34 that had been standardised using water-soluble globular proteins in 0.5% sodium deoxycholate (Fig. 1). Molecular weights were calculated from $S_{20,w}$ and Stokes radii (α) by using the relationship molecular weight = $6\pi N\alpha\eta S/1-\rho\bar{v}$ (ref. 13), where N is Avogadro's number, η the viscosity and ρ the density of water at 20 °C. The partial specific volume ($\bar{v}$) for the papain-solubilised HLA antigens was taken to be 0 72, whereas that for the deoxycholate-solubilised whole antigens was assumed to be 0.74 on the basis that they contain 8% carbohydrate (E. Appella, personal communication) and bind 0 5 g of deoxycholate per g of protein (see text). The frictional ratio (f/f_0) was calculated according to ref. 13.

asymmetrical, the possibility that the asymmetry is primarily due to the association of the bound detergent with one region of the molecule only cannot be ruled out at present.

In contrast to previous work[9,10], no evidence was obtained in the current study for the presence of dimers. It was concluded that the above results cast doubt on the validity of the 4-chain, dimeric, immunoglobulin-like model that has been proposed for membrane-bound HLA antigens, but do not rule out the possibility of a common evolutionary origin for HLA antigens and immunoglobulin.

We thank Dr A. F. Williams for the gel-filtration analysis of HLA antigens on Sephadex G-200. The water-soluble fragments of HLA antigens (type: A1, A2, B7 and B12) produced by papain digestion were donated by Dr A. R. Sanderson. This work was partly supported by an MRC grant (to the Genetics Laboratory, Oxford). P.G. is a recipient of an MRC research scholarship.

Identification of Ss protein as murine C4

DEMANT *et al.*[1] showed that the Ss-Slp region in the H–2 complex in mice affected the level of serum complement, the Ss high mouse having a higher complement activity than the Ss low mouse. They went on to show that antiserum to Ss protein could deplete complement activity from mouse serum, which has been confirmed in another laboratory[2]. This was the first association described between complement and the principal histocompatibility locus. Further associations have since come to light. In the mouse, C3 levels are controlled in part by a gene in the H–2 region[3] although the effect is not large On the other hand, the 'C5 deficiency gene' in the mouse is not linked to H–2 (ref. 4). In man the allotypes of factor B show close linkage to HLA (ref. 5). C2 deficiency in man is also HLA linked in family studies[6] and a marked linkage disequilibrium has been observed between the 'C2 deficiency gene' and the haplotype HLA10,W18. In the family described with C4 deficiency, HLA linkage has also been described[7]. The C3 allotypes in man, however, are not linked to HLA, nor is the 'C3 deficiency gene'[8]. For guinea pigs, the 'C4 deficiency gene' is linked to the principal histocompatibility locus[9]. Démant *et al.*[1] showed that the Ss protein is likely to be a complement component, and in this communication we provide evidence that the Ss protein is the murine equivalent of the fourth component, C4.

Antiserum to Ss was prepared and rendered monospecific as before[1]. Antiserum to mouse C3 was prepared as before[10] and rendered substantially monospecific by absorption with the serum of mice treated with cobra venom factor. A test of total haemolytic activity confirmed the observation that the Ss high mice had almost twice the activity seen in the Ss low mice.

Functional tests for the components that can be measured by standard functional assays for human complement[11] were undertaken as shown in Table 1. These results show several components which the Ss protein cannot be. Thus Ss is unlikely to be any of the components C5–C9 since the lytic titre of mouse serum on erythrocyte antibody complexes which reacted with the first four components of complement (EAC 1423) is somewhat higher in the serum of the Ss low mice. Similarly, the Ss protein seems not to be C1 nor either of the two factors of the alternative pathway which are required for reaction with cobra venom factor, that is factor B or factor D. Since human factor B is known to be linked to the HLA locus, the observation that the Ss protein seems not to be factor B is particularly significant The observation was confirmed by showing that anti-Ss failed to prevent the diffusion of the cobra venom C3-convertase formed on adding cobra venom factor to normal mouse serum. Depletion of factor B does not in any case decrease the total haemolytic titre of human serum (A.M. and P.J.L., unpublished). Functional tests were also carried out for the C$\bar{1}$ inhibitor and the C3b inactivator. In neither case were differences found between Ss high and Ss low mice.

Table 1 Functional complement activity in Ss high and Ss low strains of mice

	B 10.D2/N H–2^d Ss high (h-a)	B10.BR H–2^k Ss low (l-o)
CH50 per ml	8	4
C1 (titre)	1,280	1,280
C$\underline{5}$ ~ C9 (titre)	3	8
C$\underline{1}$-inhibitor (C$\bar{1}$ required to react with 100 µl serum)	20 µl	30 µl
C3b-inhibitor (titre) (measured by conglutinogen activation)	40	40
CVF-cofactors (taken as) (factors B + D)	100%	98%
C3 (antigenically)	158	180

CVF, Cobra venom factor. h-a, Ss $^{\text{high}}$ Slp^d; l-o, Ss $^{\text{low}}$ Slp^0.

Functional tests for C4, C2 and C3 were difficult to carry out with mouse serum. C3, however, could readily be measured immunochemically and, insofar as a difference was discovered among the mice tested, there was a modest increase in C3 levels in the Ss low mice. This agrees with the findings of Ferreira and Nussenzweig[3]. To attempt to identify Ss protein as either of the two remaining components—C4 and C2—experiments were carried out using an anti-Ss antiserum to detect Ss protein as a fixed complement component on erythrocytes (Table 2). When fresh mouse serum was added to EA, an intermediate was made that could be agglutinated more strongly and to higher titre with anti-Ss showing that more Ss protein has been fixed. In this experiment a C5-deficient mouse serum was also used to make EAC. This intermediate also was agglutinated (albeit weakly being a Ss low strain) by anti-Ss serum. This confirms that Ss is not a component of the complement sequence at the C5 stage or beyond.

When the EAC made with the Ss high serum was allowed to decay, either in EDTA to remove C1 as well as C2, or in half-ionic strength complement buffer to remove C2 only,

Table 2 Assessment of Ss as agglutinogen on complement-coated cells

	EAC(CBA)	EAC(AKR)	EAC(BALB/c)	EA
Ss status	l-o	l-o	h-a	
C5 status	+ve	−ve	+ve	
Agglutination titre with				
Anti-C3	729	729	729	0
Anti-Ss	1	27 (weak)	27 (strong)	0

				Agglutination titre with anti-Ss
EAC (BALB/C)		Undecayed	(EAC1423(5))	27
EAC (BALB/C)		Decayed 90 min in CFT–sucrose	(EAC143)	27
EAC (BALB/C)		Decayed 90 min in EDTA–saline	(EAC43)	27
			EA	0
EA	+	NH_3 treated BALB/c complement		0
EAC (CBA)	+	NH_3 treated BALB/c complement		1
EA	+	Heated (56 °C, 30 min) BALB/c complement		0

The figures are the highest dilutions of antiserum giving rise to agglutination. CFT, Complement fixation test buffer.

agglutination by anti-Ss was not impaired. This strongly suggests that the Ss protein is C4. A further experiment was performed to confirm this conclusion. EAC was made with Ss low serum and subsequently incubated with NH_3-treated Ss high serum. This conferred on the intermediate no further reactivity with anti-Ss This experiment indicates that Ss is not C2. The same experiment can also be taken as evidence that Ss is not properdin because activated properdin will attach to fixed C3b (ref. 12).

Table 3 Assessment of Ss by haemagglutination inhibition

Strain		Ss status	Dilution of serum inhibiting agglutination of EAC (BALB/c) by 3 agglutinating doses of anti-Ss
C3H/He/j	♂	l-o	20
CSW	♂	h-a	140
B10.A	♂	h-a	140
B10.D2/n	♂	h-a	240
B10.BR	♂	l-o	20
BALB/c	♂	h-a	140
BALB/c	♀	h-a	80
CBA	♀	l-o	30

Using EAC made with the Ss high serum and three minimum haemagglutinating doses of anti-Ss serum, we could assay the Ss level of several mouse sera by haemagglutination inhibition. Although such experiments are complicated by the presence of immunoconglutinins in individual mouse sera, Table 3 shows that it is possible to get a measure of the concentration of Ss in serum by this technique. This would confirm that the antigen detected by the anti-Ss serum on EAC is the same as that normally measured by precipitation.

These experiments show that the protein reacting with anti-Ss antiserum is a complement component bound firmly and stably to EA at a stage before C5 and that the properties of the Ss 'agglutinogen' correspond to what is anticipated for C4.

In view of the probability that the structural genes for several complement components are coded in the H–2 region, the possibility should not be wholly discounted that the method used to raise anti-Ss antisera could raise antibodies to more than one complement protein. It might therefore be preferable to say that murine C4 is an Ss protein rather than necessarily the unique Ss protein.

H–2 linked Ss protein is C4 component of complement

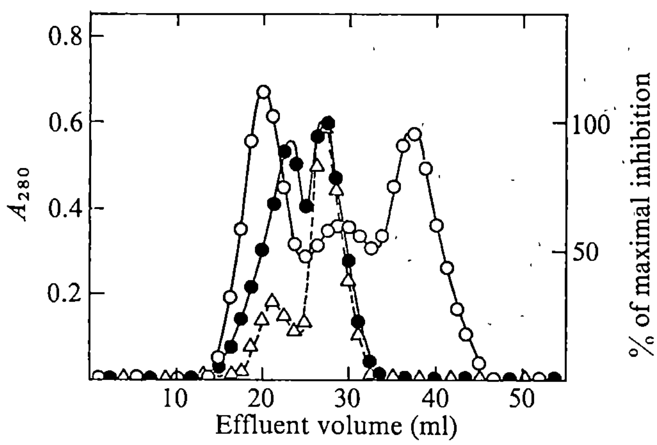
THE major histocompatibility complex in the mouse encompasses several distinct loci, which, with one exception, control the expression of cell surface glycoproteins. The exception is the Ss-Slp traits[1]. The Ss trait involves regulation of the level of a plasma protein, the Ss protein[2]. The S region of the H–2 complex, whose marker gene controls the Ss-protein concentration, also regulates the haemolytic complement level[3]. This has led to the suggestion that the Ss protein is a component of complement[3,4]. We have isolated the Ss protein and demonstrate here that it is the murine equivalent of C4.

In our initial attempts to purify the Ss protein we used conventional fractionation procedures. Serum from male BALB/c mice (*Ss*^{h} genotype) was initially separated by Sephadex G-200 gel chromatography followed by successive steps of DEAE–Sephadex ion-exchange chromatography (twice), and as the final purification step, recycling chromatography on Sephadex G-200. Ss protein was monitored in chromatographic fractions by immunodiffusion analyses, using a rabbit antiserum against a high molecular weight plasma protein fraction from BALB/c serum. The antiserum was rendered monospecific by repeated absorptions with serum from CBA (Ss^l phenotype) male mice[2]. The isolated protein was homogeneous and of high purity as shown by several physicochemical, chemical and immunological criteria (L.S., in preparation). It consisted of four polypeptide chains, each of apparent molecular weight about 35,000, which were held together in pairs by disulphide bonds. But during the isolation procedure the molecular weight of Ss protein became considerably smaller. Sedimentation–diffusion analyses of the Ss protein present in unfractioned plasma suggested a molecular weight of about 200,000 compared with the 140,000-dalton molecule isolated. It thus seemed likely that either the Ss protein in plasma is linked to another protein, which was lost during isolation, or is the Ss protein proteolytically degraded during isolation. We therefore tried to improve the isolation by speeding it up. A rabbit antiserum was raised against the 140,000-dalton component. This antiserum reacted with a single component in plasma, as shown by extensive immunodiffusion and immunoelectrophoretic analyses. A radioimmunoassay developed with this antiserum (L.S., in preparation) showed that male mice contained about twice as much of the Ss protein as did female mice, regardless of strain. Furthermore, strains with the Ss^h haplotype had approximately 10 times more of the isolated component in serum than mice of the Ss^1 genotype. These data strongly support the view that the antiserum is directed against the Ss protein[1].

The IgG fraction of the anti-Ss-protein serum was coupled covalently to Sepharose 4-B to obtain an immunosorbent column. The Ss protein was isolated from EDTA-plasma, which had first been passed over a column of Sepharose 4-B coupled with aggregated rabbit IgG to remove material sticking nonspecifically to IgG. The breakthrough peak recovered from the aggregated Ig column, which contained all the immunologically active Ss protein as measured by radioimmunoassay, was subsequently passed over the anti-Ss column. The bound material, which was desorbed by lowering the *p*H of the eluent, was labelled with ^{125}I and analysed by sodium dodecyl sulphate (SDS)–polyacrylamide gel electrophoresis and by gel chromatography in 6 M guanidine hydrochloride. A single component with an apparent molecular weight of slightly less than 200,000 was obtained from the anti-Ss column. On reduction and alkylation in denaturing conditions, the Ss protein resolved into three (or sometimes four) distinct polypeptide chains. Two of the chains appeared in the 70,000–80,000-dalton region on a column equilibrated with 6 M guanidine hydrochloride. The third chain had an apparent molecular weight of about 23,000 and in some preparations small amounts of a 13,000-dalton component was present. It is thus reasonable to conclude that the Ss protein isolated by conventional techniques most likely represents a proteolytically derived fragment of the larger molecule.

The molecular characteristics of the immunosorbent-purified protein suggested that if indeed it is a component of complement it most likely is C3, C4 or C5, on the reasonable assumption that mouse and human complement components are similar in structure[5]. Since mouse strains genetically deficient in C5 may have the Ss^h genotype[6], C5 could be ruled out as the Ss protein. The level of C3 was estimated by single radial immunodiffusion of serum from three strains with the Ss^l genotype and five with the Ss^h genotype. No statistically significant difference in the serum concentration of C3 was found. Although it has been claimed that the level of C3 is regulated in part by the H–2 complex, even in that study no correlation was found between the *Ss* genotype and the level of C3 (ref. 7).

Fig. 1 Gel chromatography of BALB/c male serum on a Sephadex G-200 column (76×1 cm) equilibrated with 0 02 M Tris-HCl buffer, *p*H 8.0, containing 0.15 M NaCl. Total protein was estimated by absorbance at 280 nm (○). The distribution in the effluent of Ss-protein-reacting material was assessed by radioimmunoassay with the 140,000-dalton fragments of the Ss protein as the ^{125}I-labelled component and with antiserum against the Ss protein (●) or human C4 (△) as the binding reagent.



Our efforts were therefore concentrated on the possible relationship between C4 and the Ss protein. Human C4 was isolated[8] and its molecular characteristics were compared with those of the Ss protein. The human C4 had a molecular weight on SDS–polyacrylamide gel electrophoresis very similar, if not identical, to that of the immunosorbent-purified Ss protein. When human C4 is reduced and alkylated two large polypeptide chains are released. Their molecular weights were indistinguishable from those of the main Ss-protein chains. Furthermore human C4 contained a polypeptide chain with an apparent molecular weight of 35,000 in contrast to the 23,000-dalton component derived from the Ss protein. This discrepancy in the polypeptide chain structure between the two proteins may be genuine, but could have arisen because different isolation procedures were used. It should be remembered that serum contains a C4b inactivator which sequentially cleaves C4 into smaller fragments[9].

To examine further the relationship between human C4 and the Ss protein, the possibility of immunological cross reactivity was examined. A sensitive radioimmunoassay for human C4 was developed since in immunodiffusion analyses anti-Ss did not precipitate human C4 and vice versa. It could however, be shown that the binding of ^{125}I-labelled C4 to a monospecific antiserum against human C4 was almost abolished in the presence of immunosorbent-purified Ss protein. In the Ss protein radioimmunoassay human C4 competed very efficiently with ^{125}I-labelled Ss protein for binding to the antibodies. The specificity of the reactions was examined by monitoring the occurrence of the Ss protein in fractions obtained after gel chromatography of mouse serum on a column of Sephadex G-200 Figure 1 shows two peaks of Ss-protein-reacting material produced in the Ss protein radioimmunoassay. The same distribution of material was obtained when antibodies against human C4 were used, and similar patterns were recorded even when ^{125}I-labelled human C4 was used. These data strongly suggest that Ss protein is murine C4. The earliest eluted Ss-protein-containing peak is greatly diminished, with a concomitant increase in the amount of Ss protein present in the second peak, in EDTA-plasma. The high molecular weight of the Ss-protein-reacting material in the first peak (sedimentation coefficient about 18S) may represent Ss protein bound to other components, especially since it is known that in fluid phase C423 may occur[10].

To identify the Ss protein unequivocally it must be shown to reconstitute functionally a C4-deficient serum (R4-serum) We have so far failed to do this. The drastic elution conditions that have to be used to desorb the Ss protein from the immunosorbent column may derange the protein so that when it is recovered it is inactive. We were able, however, to test whether Ss-depleted serum was deficient in C4. Figure 2 shows that the material that passed over the anti-Ig column had substantial C4 activity whereas the Ss-protein-depleted fraction was devoid of functional C4 (Fig. 2). This seems to identify the Ss protein functionally with C4.

Lachmann *et al.* in the preceding communication[11] examined the relationship between the *Ss* genotype and various complement components in functional complement assays. Using an antiserum rendered specific for Ss protein, they assessed by absorption the presence of Ss on cells coated with complement. Although using a different

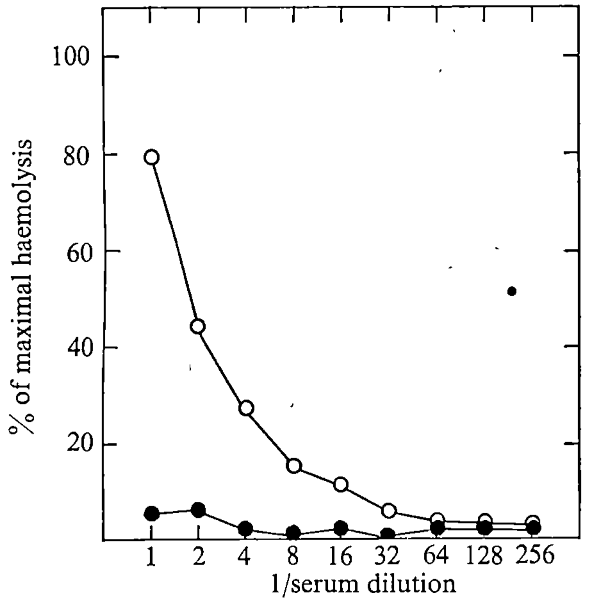


Fig. 2 Reconstitution of the haemolytic complement activity of C4-deficient guinea pig serum with Ig (○) or Ss protein (●) depleted BALB/c male EDTA-plasma. Aliquots of the mouse plasma were depleted of Ig and Ss protein, respectively, by passage over immunosorbent columns containing covalently bound antibodies of the appropriate specificities. The breakthrough peaks recovered from the immunosorbent fractionations were concentrated separately, dialysed against veronal buffer, and adjusted to the original volume of the plasma sample. Guinea pig serum was depleted of C4 by NH_3 treatment (R4 serum). EA was obtained by mixing sheep red blood cells (SRBC) with the IgM fraction of a rat antiserum against SRBC. Haemolytic complement assay was performed as follows. To 100 µl of R4 serum, diluted 1/20 in gelatin-containing veronal buffer, 100 µl of the relevant mouse plasma fractions, depleted of Ig or Ss protein, at the indicated dilutions, and 50 µl of 1% EA were added. After incubation at 37 °C for 30 min, the mixtures were diluted with 1 ml of cold veronal buffer. The cells were pelleted by centrifugation at 400*g* for 10 min and the absorbance at 415 nm in the supernatant was estimated. The 100% value in the figure is taken as the absorbance obtained in the complement assay with untreated BALB/c EDTA-plasma. For all values blank readings have been subtracted.

approach than the present, their study demonstrates that the Ss-protein is murine C4.

Our data reinforce the importance of the H-2 region in various immunobiological systems. As well as its role in cell mediated immunity, the major histocompatibility complex now seems to be involved in an effector function of the humoral immunity system. Not only C4 but C2 (ref. 12), C3 (ref. 7) and factor B of the alternate pathway[13] are regulated by this gene complex. Whether it also controls other components of the complement system remains to be elucidated. We thank Dr P. J. Lachmann for communicating his data before publication. Influence of negative lipids on interactions between artificial membranes and cholinergic drugs

EFFORTS have been made to incorporate "cholinergic systems" into artificial lipid membranes[1–5]. In all cases, material was obtained from animal tissues and incorporated into artificial systems, cholinergic drugs were added to the bathing solutions and different "permeability changes" were described. The available information on the interactions between pure lipid membrane and cholinergic agents is, however, scarce[6] and to establish the role of proteins and lipids in the reported findings is difficult. We report here results showing that a negatively charged lipid induces "cholinergic reactivity" in artificial lipid membranes which can be prevented by *d*-tubocurarine.

Planar artificial lipid membranes were made in a septum separating two aqueous phases. Increasing voltages were applied from an external d.c. source and the membrane resistance was calculated from the current–voltage relationship which was constant between 0 and 150 mV. Different salt gradients were then established across the membrane

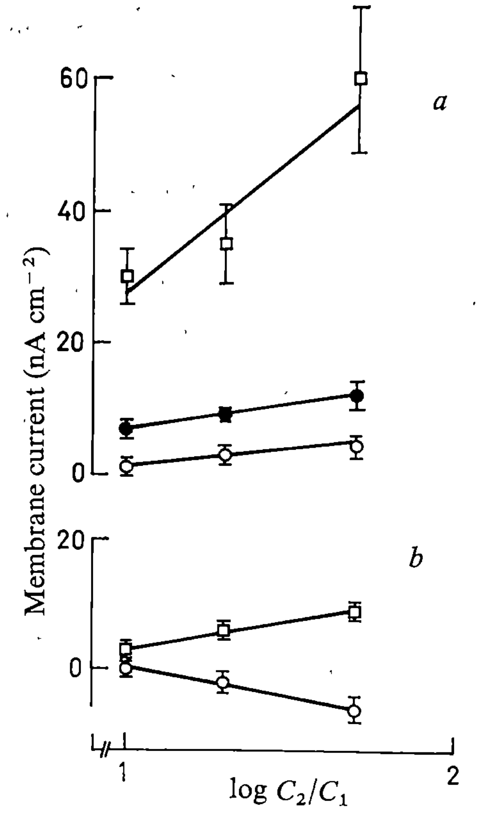

Fig. 1 Membrane current (voltage clamped at 0 mV) as a function of AChCl gradients across the membrane. *a*, Control; *b*, in the presence of *d*-TCCl (10^{-4}M) in the bath. ○, PC plus cholesterol membranes; ●, PC, cholesterol and 1% PS; □, PC, cholesterol + 10% PS.

maintaining the potential clamped at 0 mV. The current flowing through the membrane was recorded and the corresponding membrane potential was calculated using the previously determined resistance. A detailed description of this technique was made elsewhere[7]. The membrane-forming solutions contained 2.3 mg ml^{-1} synthetic DL-α-dipalmytoyl lecithin (PC) (Sigma, standard for chromatography), 2.3 mg ml^{-1} synthetic cholesterol (Sigma, 99%) and, in some cases, different amounts of bovine phosphatidyl-L-serine (PS) (Sigma, 95%) dissolved in chloroform–methanol–tetradecane (1.0 : 0.8 : 0.5; v/v).

Table 1 Calculated potentials for a tenfold salt gradient across the membrane (mV)

	100% PC	99% PC–1% PS	90% PC–10% PS
AchCl	−1.6±2.0	−8.4±1.1	−20.2±1.3
ChCl	−1.2±0.6	−4.5±0.4	−17.9±1.4
d-TCCl	−8.6±2.1	−13.6±2.8	−33.4±6.1
NaCl	+12.6±3.5	+7.4±1.2	−30.1±2.8

The negative sign indicates cationic selectivity and the positive sign indicates anionic selectivity. Membrane potentials were calculated from membrane current and membrane resistance.

Figure 1*a* shows the current that flows through the membrane when different acetylcholine chloride (AChCl) (Sigma, preweighed vials, 99%) gradients were established. The membranes were prepared in the presence of 1 mM AChCl solution buffered with 1 mM Tris-PO$_4$ (*p*H 7, at room temperature). It can be observed that current intensity is a linear function of the logarithm of the ratio of AChCl concentration in the two chambers. The corresponding membrane potentials are shown in Table 1. The membrane solution used contained as amphipathic molecule only PC, PC plus 1% PS or PC plus 10% PS. It can be observed that as PS concentration increases, membrane current and membrane potential become greater. The sign of the potential indicates cationic selectivity. These results show that, specially in the presence of negative lipids, AChCl gradients at high concentrations can induce cationic membrane potentials showing Nernst-type behaviour. This AChCl potential can be blocked by *d*-tubocurarine (*d*-TCCl). Membranes were made in the presence of 10^{-4} M *d*-TCCl (Sigma) and different AChCl gradients were applied. Figures 1*a* and *b* compare results with membranes containing only PC or PC plus 10% PS with or without *d*-TCCl in the bath.

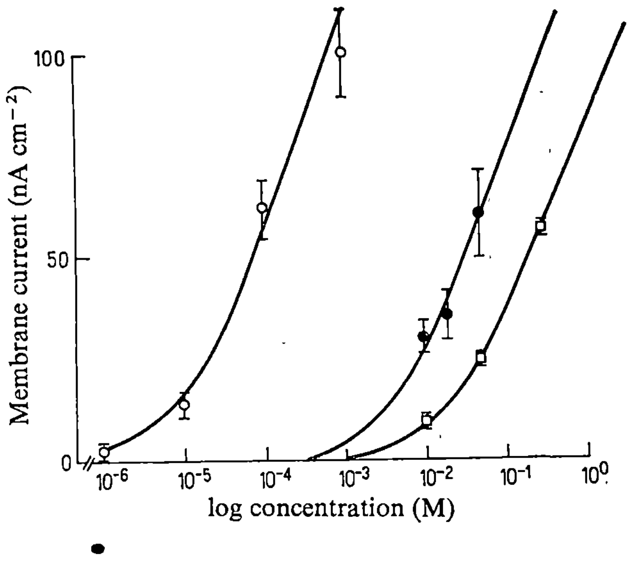

Fig. 2 Membrane current (voltage clamped at 0 mV) as a function of the concentrations of different agents on one side. ○, *d*-TCCl; ●, AChCl; □, NaCl. The membranes were initially made in 1 mM Tris-PO$_4$ buffer. The *d*-TCCl curve was drawn according to the experimental points. The AChCl and NaCl curves were obtained by moving the *d*-TCCl curve to the right.

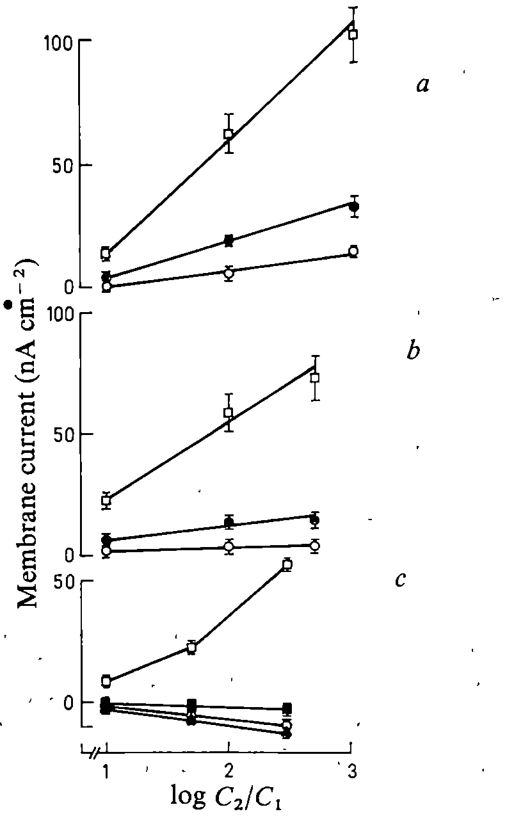

Fig. 3 Membrane current (voltage clamped at 0 mV) as a function of different gradients. ○, PC + cholesterol membranes; ●, PC, cholesterol and 1% PS; □, PC, cholesterol and 10% PS; ▲, PC + cholesterol in the presence of *d*-TCCl (10^{-4}M); ■, PC, cholesterol and 10% PS in the presence of *d*-TCCl (10^{-4}M). *a*, *d*-TCCl gradients; *b*, ChCl gradients; *c*, NaCl gradients.

To interpret these results AChCl, *d*-TCCl and NaCl gradients were established across membranes containing different proportions of PS. Membranes were made in 1 mM Tris-PO$_4$ (*p*H 7.0) and the tested salts were added to one side of the membrane at increasing concentrations. Figure 2 shows the results obtained. In the presence of 10% PS NaCl, AChCl or *d*-TCCl induce cationic potentials. The concentration ranges in which this phenomenon is apparent are, however, quite different. These results could be explained by a different effective concentration for each one of these species at the membrane interface. Assuming that *d*-TCCl accumulates at the surface of the membrane to a larger extent than either AChCl or NaCl, its blocking effect becomes predictable.

The membrane potentials induced by the presence of *d*-TCCl gradients are also sensitive to PS concentrations (Fig. 3*a*; Table 1) and it can be remarked that in the case of *d*-TCCl even in the presence of an amphoteric phospholipid (PC) a clear cationic selectivity was observed.

In a previous work[8] a difference between choline chloride (ChCl) and AChCl responses was reported when natural extracts were used. This is not the case in this system. Figure 3b and Table 1 indicate that the behaviour in the presence of ChCl is not distinguishable from the behaviour when AChCl is tested.

It has been reported that the membrane potential developed when a NaCl gradient is established across undoped membranes is a function of the net charge of the lipids[9] used. We have shown that a low percentage of PS is sufficient to develop cationic selectivity (Figure 3*c*), although, in practice, pure PC membranes did not discriminate between cations and anions.

The present results show that pure lipid membranes containing a small amount of negative lipids can show cationic selectivity. Furthermore, when the salt gradients are established with cholinergic agents, membrane potentials occur which also show cationic selectivity. The cationic selectivity could be due to a higher permeability for these organic cations when negative lipids are present. Adsorption potentials probably arise, however, at the membrane interface and, consequently, it is not possible to know whether or not a local equilibrium exists at the interface. If the calculated potentials are equal to a distribution potential, or an adsorption potential cannot be established in our experimental conditions[10], these potentials would be similar to those described by Bean *et al.*[11] when procaine or other organic molecule gradients were applied across membranes containing brain lipids (whose proportion of negative lipids was not reported).

These types of interactions could be the cause, at least in some cases, of the "cholinergic responses" obtained with membranes containing natural extracts. This is especially true in the case of *d*-TCCl, generally used at concentrations similar to those used here[2,4,5]. It has been reported that proteolipids could have an important role in cholinergic systems[12] and it is also known that these molecules are rich in negative lipids. When AChCl is applied on artificial membranes containing proteolipids from electric eel a "conductance change" appears, which can be abolished by *d*-TCCl[8]. In view of our results the role of membrane potentials due to the presence of negative lipids must be taken into account when interpreting these type of experiments. Similarly, the *d*-TCCl-dependent membrane potential observed when salt gradients are established across proteolipid containing membranes[7] could be also dependent on the presence of negative lipids. We can speculate that proteolipids induce negatively charged clusters in the membrane that favour the adsorption of different cations. The role of the interactions described here in the pre- or post-synaptic systems is a matter of discussion.

Competition for sulphate during detoxification in the gut wall

ALTHOUGH the absorptive function of intestinal cells has been studied in depth, the capacity of intestinal mucosa to metabolise ingested substances has received less attention. But the gut wall presents a first line of defence against potentially harmful agents and it is likely that its detoxifying properties are important.

Gut cells are capable of oxidative, reductive, hydrolytic and various synthetic reactions, including acetylation and conjugation with sulphate and glucuronic acid[1]. There are relatively few quantitative data on drug metabolism within the gut mucosa but Conolly *et al*[2] demonstrated that the β agonist isoprenaline, administered orally, is excreted principally in the urine as an ethereal sulphate, and their experiments suggested that conjugation took place within the gut wall. Intravenous isoprenaline was excreted in the urine largely unchanged. Sulphate conjugation greatly reduces the systemic availability of isoprenaline which can produce pharmacological effects in μg quantities intravenously[3], but which is used in mg amounts as an oral drug[4]. George, *et al.*[5] showed that when isoprenaline is placed in an isolated dog gut loop *in situ*, only a small fraction appears as free isoprenaline in the venous effluent draining the loop, the major proportion being a sulphate conjugate. They also demonstrated that inclusion of salicylamide with isoprenaline in the loop resulted in greatly increased concentrations of free isoprenaline in the venous effluent. Salicylamide is also metabolised by sulphate conjugation[6], and their findings suggested that competition for available sulphate in gut wall enabled more free isoprenaline to drain from the gut. We have investigated this possibility in the intact animal.

Seven female greyhound dogs (20–34 kg) were placed in a restraining stand and remained conscious throughout the experiment. Heart rate was recorded by electrocardiograph. On a control day, after heart rate had stabilised, each dog was given isoprenaline, 3.0 mg base in 200 ml of water by stomach tube. Four dogs also received ^{3}H-isoprenaline (+Isoprenaline-(7^{3}H)-HCl, 1.8 Ci mg^{-1}, Radiochemical Centre, Amersham) and their plasma isoprenaline was measured[2] in systemic venous blood. Heart rate was recorded for 180 min On a test day, atfer approximately 10 d, the experiment was repeated except that 600 mg of salicylamide was given with isoprenaline. Five of the dogs also received 600 mg of salicylamide in gelatin capsules by mouth 2 h and 1 h before isoprenaline and salicylamide. Three of the dogs were later given 600 mg of salicylamide and 1.0 g of L-cysteine by mouth 2 h and 1 h before receiving a solution containing 1.0 g of L-cysteine, isoprenaline and salicylamide, by stomach tube.

When isoprenaline alone was given, the mean peak plasma isoprenaline concentration was 2.02±0.28 (s.e.m.) ng ml^{-1} and the area under the plasma isoprenaline–time curve was 211.7±32.2 ng ml^{-1} min. After isoprenaline had been given with salicylamide, peak plasma concentration

Table 1 Peak heart rate responses (beats min^{-1}) and areas under heart rate–time curves (beat min^{-1}) in seven conscious dogs given isoprenaline (3.0 mg base), salicylamide (600 mg) or L-cysteine (1.0 g) by mouth as indicated

	Area	2,120.4	4,634.7	2,512.6

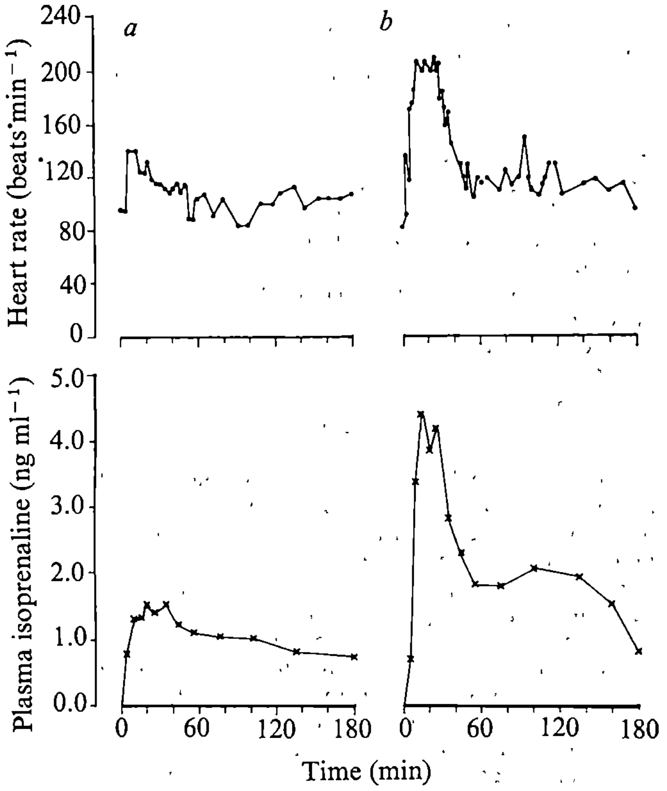

Fig. 1 Plasma free isoprenaline and heart rate responses in a conscious greyhound which received: *a*, isoprenaline (3.0 mg base) or *b*, isoprenaline (3.0 mg base) with salicylamide (600 mg) on separate days.

was greater in each animal (mean 4.67±1.38 ng ml^{-1}) as was the area under the plasma isoprenaline–time curve (mean 386.9±50.6 ng ml^{-1} min). The results of a typical experiment are shown in Fig. 1.

In each animal the heart rate response, expressed as the peak heart rate from baseline and as the area under the heart rate-time curve calculated by trapezoidal rule, was greater when isoprenaline was given with salicylamide than when it was given alone (Table 1). In three animals given L-cysteine with isoprenaline and salicylamide, heart rate responses were less than those for isoprenaline and salicylamide and were similar to the responses for isoprenaline alone.

To assess whether salicylamide has any direct effect on the responsiveness of the dog heart to isoprenaline, an intravenous infusion of isoprenaline sulphate, 0.019 μg (base) kg^{-1} min^{-1}, was given to a conscious dog which had received atropine, 40 μg kg^{-1}, intravenously. When a stable increase in heart rate had been achieved, 80 mg of salicylamide was given intravenously. The mean (±s.d.) heart rate was 134±14 beats min^{-1} for 12.5 min before salicylamide and 130±12 beats min^{-1} for 12.5 min after salicylamide. These results are not significantly different at the 5% level of probability.

Sulphate exists in an activated form in the gut[7] and under the influence of sulphokinases, which exist throughout the gut[8], it can react with many substances, especially those with phenolic groupings. Salicylamide is metabolised principally to sulphate and glucuronide conjugates, and Levy and Matsuzawa[6] showed in man that the fraction of the dose excreted as salicylamide sulphate decreased markedly as the oral dose of salicylamide was increased from 75 to 2,000 mg. They also showed that co-administration of L-cysteine, which is catabolised to inorganic sulphate, restored the conjugation of salicylamide even at high doses, indicating that the capacity was limited by the availability of sulphate. It seems likely that the explanation for the increased plasma isoprenaline and increased cardiac responses when isoprenaline and salicylamide were administered together lies in competition between the two compounds for available sulphate in gut mucosa, enabling more free isoprenaline to reach the systemic circulation. The reduced cardiac response when L-cysteine was administered with salicylamide and isoprenaline is consistent with this hypothesis since availability of sulphate would not in this case be rate limiting. Thus the systemic availability of oral isoprenaline which is normally limited by metabolism in the gut wall can be increased by co-administration of another drug which shares its route of metabolism. Moreover, we have found that the increased availability and pharmacological effects are of considerable magnitude.

Although isoprenaline is commonly administered by inhalation of an aerosol, most of an inhaled dose is known to be swallowed and absorbed through the gut[9]. We have no evidence of interaction between isoprenaline or similar drugs and salicylamide in clinical use, but events of this type may be difficult to identify. One reason may be self-medication, for salicylamide is a constituent of some proprietary mixtures obtainable without prescription. Indeed it is possible that ascorbic acid (vitamin C) which can reduce the conversion of salicylamide to salicylamide sulphate[10], and paracetamol[11] which can compete with salicylamide for sulphate may also reduce the sulphate conjugation of isoprenaline, and both these substances are readily available to the public. Thus interactions between sympathomimetics which form conjugates with sulphate and other drugs which are similarly metabolised, seem to be a realistic possibility and would be potentially dangerous.

It is interesting that no clear explanation has been found for the rise in asthma deaths associated with the use of aerosol bronchodilators[12]. The interaction we describe illustrates a mechanism whereby toxic amounts of sympathomimetic drugs, even administered by aerosol, may reach the systemic circulation. Viewed from a different aspect, competition between substances which are metabolised by conversion to sulphate conjugates might be used to enhance the availability and therapeutic usefulness of a drug which is normally inactivated by gut mucosa.

Caffeine inhibits cell transformation by 4-nitroquinoline-1-oxide

SOMATIC mutation has been considered a likely initiating step in chemical carcinogenesis[1–3], chiefly because of the close correlation between the mutagenic and carcinogenic activity of various chemicals[4–6]. Study of cells from patients with disease predisposing to a high incidence of cancer, such as xeroderma pigmentosum and Fanconi's anaemia, has suggested that defective DNA repair is correlated with this predisposition to malignant transformation. When cells are transformed by 3-methylcholanthrene[7], 4-nitroquinoline-1-oxide (4NQO)[8], or X irradiation[9–11], division is necessary soon after treatment to fix the transformation: if treated cells are unable to grow the transformation is not fixed. These results could be explained if DNA damage induced by a carcinogen is converted into a stable and replicable structural change only by means of DNA replication before the intervention of error-free repair mechanisms. The model of mutagenesis[12–14] based on evidence obtained with micro-organisms suggests that errors introduced by an error-prone postreplication repair mechanism are the principal source of mutation. Furthermore, caffeine inhibits "postreplication repair" (presumably an error-prone mechanism) but not excision repair (presumably error-free) in rodent cells[15–19]. I now report that caffeine reduces the transformation frequency of mouse cells treated with 4NQO. This supports the somatic mutation theory of cell transformation.

Malignant transformation was assayed in A31-714 cells, a subclone isolated from BALB/3T3-A31 clone, and 4NQO which induces transformation in these cells after a short exposure[20]. Actively growing cells were treated with 4NQO for 30 min in suspension, washed and then plated into 60-mm plastic dishes containing 5 ml of Eagle's minimal essential medium supplemented with 10% newborn or foetal bovine serum. Plating efficiency was determined 10 d later, and transformation was scored 30 d after treatment as described previously[20]. Caffeine was dissolved in Dulbecco's PBS, filtered, and added to culture medium. Because of the need for cell proliferation for the fixation and expression of transformation[8], plating efficiency was determined initially for all experimental conditions, and then the number of cells plated was adjusted, so that the average number of divisions required to reach confluence for the surviving cells was nearly the same in all dishes.

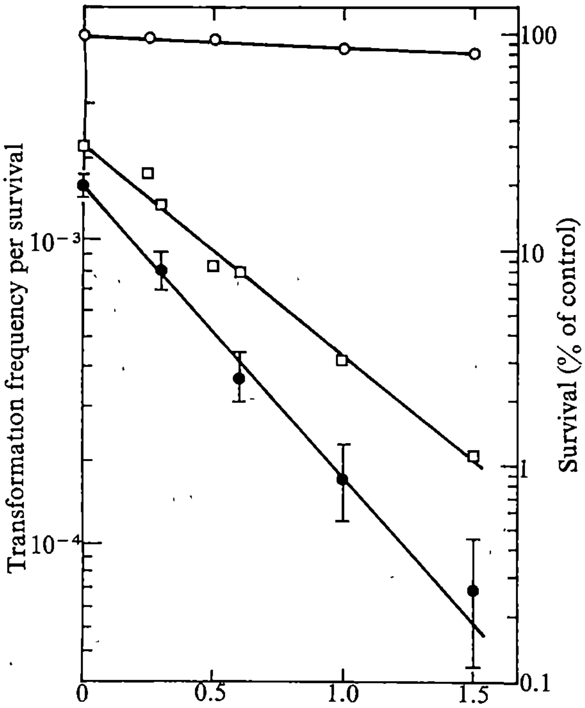

Fig. 1 Survival and transformation frequency in A31-714 mouse cells treated with 4NQO and subsequently incubated with various concentrations of caffeine. The graph shows surviving fraction of untreated (○), and of 4NQO-treated cells (□); transformation frequency (mean ± s.e.) of 4NQO-treated cells (●). Actively growing cells were treated with 4NQO (0.1 µg ml^{-1}) for 30 min in suspension, washed with Dulbecco's PBS, and plated at an inoculum such that about 1×10^4 cells per 5-cm dish survived for the transformation assay and 30–100 cells per dish survived for the assay of plating efficiency. Caffeine was present in the culture medium for the first 48 h after plating. The medium was then replaced with fresh, caffeine-free medium and was subsequently changed twice a week. Dishes were then fixed with methanol and stained with Giemsa either 10 or 30 d after plating and scored for plating efficiency and transformation frequency, respectively. The s.e. of the plating efficiency was always less than 3% of the corresponding mean value.

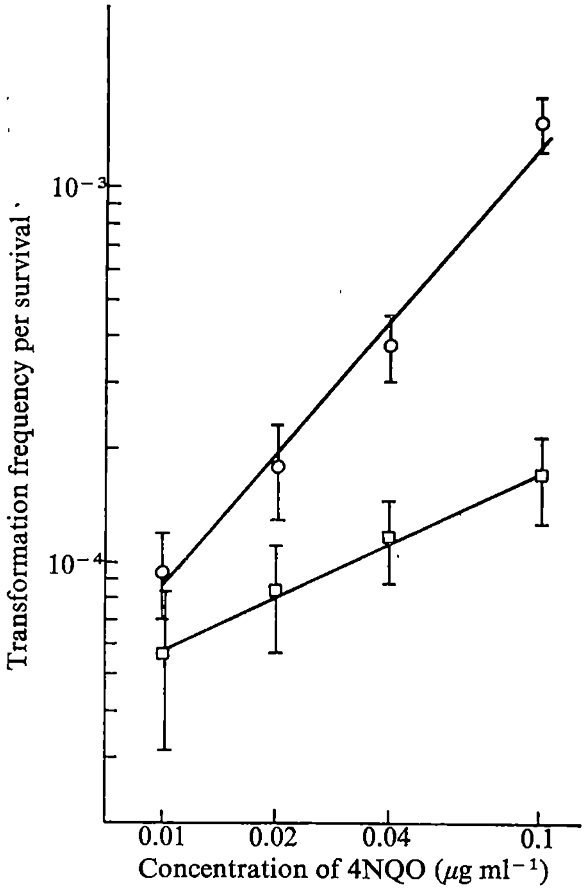

Fig. 2 Transformation frequency (mean ± s.e.) in A31-714 mouse cells treated with various concentrations of 4NQO in the presence (□) or absence (○) of 1 mM caffeine for 48 h after treatent were 4NQO. See legend to Fig. 1.

Figure 1 shows the dose–response curves for both transformation and survival of A31-714 cells treated with 4NQO (0.1 µg ml^{-1}) in the presence or absence of caffeine for the first 48 h after treatment. The upper two curves, which represent cell survival, show that caffeine reduced the survival of treated cells but not that of untreated cells. Transformation frequency per surviving cell, shown by the lower curve with the vertical bars, was also reduced by caffeine. Both survival and transformation frequency of treated cells were inversely proportional to the concentration of caffeine and almost parallel within the range of concentrations of caffeine tested. As Fig. 2 shows, the inhibitory effect of caffeine on transformation frequency was also dependent on the concentration of 4NQO.

The exposure of caffeine to cells before, or 48 h after treatment with 4NQO (0.1 µg ml^{-1} for 30 min) had no marked effect on survival and transformation frequency (Table 1). The presence of caffeine for the first 24 h after treatment with 4NQO caused much more reduction in survival and transformation frequency than in successive 24 h periods (Table 1). When the transformation frequency was calculated on the basis of the number of cells inoculated, the inhibitory effect of caffeine was even greater (not shown). In the conditions of my experiment, most cells which did not grow rapidly became detached from the substrate, so that 24 h after plating less than 10^5 cells per dish were attached to the substrate, and less than 2×10^4 cells per dish were attached after 48 h. As reported previously[8], these cell densities affect neither the fixation nor the expression of transformed state.

My results are apparently consistent with the finding that caffeine inhibits tumour induction by ultraviolet irradiation in mice *in vivo*[21]. The discrepancy between my results and those of Donovan and DiPaolo[22], in which caffeine appeared to enhance the chemically induced morphological transformation of hamster embryonic cells, may be due to differences between the transformation assays used, or to the length of time and the sequence of carcinogen and caffeine treatment In their experiments, cells were exposed to carcinogens for 48–49 h simultaneously with, or beginning 1 h before, addition of caffeine.

Table 1 Survival and transformation frequency of 4NQO-treated A31-714 cells in the presence of caffeine added at various times

Presence of 1 mM caffeine (h after 4NQO-treatment)	Plating efficiency 10 d after treatment (%)	Transformation frequency per survival* ($\times10^{-4}$)
	26	12.7±1.7
−24–0	23	13.9±1.7
0–48	2.4	1.5±0.4
0–96	1 9	1.8±0.6
48–96	16	12 5±2.3
0–24	4.1	3.0±0.8
24–48	11	6.5±1.1

*Mean±s.e.

In mammalian cells, the most marked effect of caffeine is its potentiation of cell killing and induction of chromosome aberrations by ultraviolet light and alkylating agents[23]. These are caused by low doses of caffeine, which by themselves do not have significant effects on cell survival, as my experiments have also shown. It has been suggested that this synergistic effect of caffeine is due to its inhibition of "postreplication repair", because all results reported so far show that caffene inhibits the elongation of newly synthesised daughter strand DNA after ultraviolet irradiation of rodent cells[15–19]. With the A31-714 cells used in this experiment, 1 mM caffeine does not inhibit 4NQO-induced unscheduled DNA synthesis[24]. I suggest that the reduction by caffeine of survival and transformation frequency of 4NQO-treated A31-714 cells is related to the observation that caffeine inhibits "postreplication repair" in mouse cells. Thus if "postreplication repair" is a viable error-prone repair mechanism, its inhibition would be expected to have the results reported here. This is compatible with the suggestions that (1) cell division soon after carcinogen treatment is required for the fixation of transformation[7–11], and (2) late G_1 cells show the highest frequency of transformation by radiomimetic alkylating agent[25].

My results seem to support the repair–error hypothesis[14,24,26] as a mechanism for chemical and physical carcinogenesis According to this hypothesis, carcinogen-induced DNA damage can be repaired by at least two repair mechanisms, one sensitive to caffeine and the other not. The former may be equivalent to the so-called "postreplication repair" which occurs chiefly during or soon after DNA replication and is presumed to be error prone. The latter, however, may be equivalent to excision repair which occurs throughout the cell cycle, and is presumed to be error free. The errors in the former repair system would then be the main source of mutations, some of which may lead to cell transformation.

I thank Dr C W. Dingman for reviewing the manuscript, Drs S. Kondo and K. Toyoshima for valuable suggestions, and Mrs B. Heifetz for typing the manuscript. This work was supported in part by grants from the Ministry of Education of Japan.

Local membrane current in *Limulus* photoreceptors

IT has been shown[1] that when part of a cell of the ventral photoreceptors of *Limulus* is illuminated, light adaptation is localised to the region of illumination. Since, in the vertebrate retina, there is a well known component of adaptation that is correlated with pigment concentration[2–4], local adaptation in *Limulus* may similarly be related to pigment bleaching in the illuminated region of the photoreceptor. This has been shown to be improbable, however, by experiments which indicate that adaptation in the photoreceptor is unrelated to the recovery of the visual pigment[5,6].

Another possibility is that local adaptation is related to some process that is initiated by the visual pigment. Voltage clamp studies on ventral photoreceptors[7] have shown that illumination initiates an inward flow of membrane current, brought about by an increase in the underlying conductance. If the inward current and the underlying conductance increase were localised to the region of illumination, then it might be possible that either, or both, of these processes are in some way responsible for local adaptation. We have therefore attempted to demonstrate directly the flow of local membrane current in the ventral photoreceptors of *Limulus*.

The ventral photoreceptors are located on the so-called lateral 'olfactory' nerve, which was removed from the animal, desheathed, and pinned to the bottom of a chamber with a transparent base. A photoreceptor was stimulated from below, using an optical bench so that a small movable spot of light (nominally 30 μm diameter in these experiments) could be positioned anywhere on these large photoreceptors (typically 50×150 μm in cross section[8]). Under visual control (×400 compound microscope), a portion of a single photoreceptor was gently drawn into a glass suction electrode. Then a KCl filled micropipette (resistance, 10–30Ω measured in the Ringer that bathed the preparation) was inserted into the cell. We were thus able to measure, simultaneously, the extracellular currents using the suction electrode, and the receptor transmembrane potential using the intracellular pipette. Figure 1*b* shows a

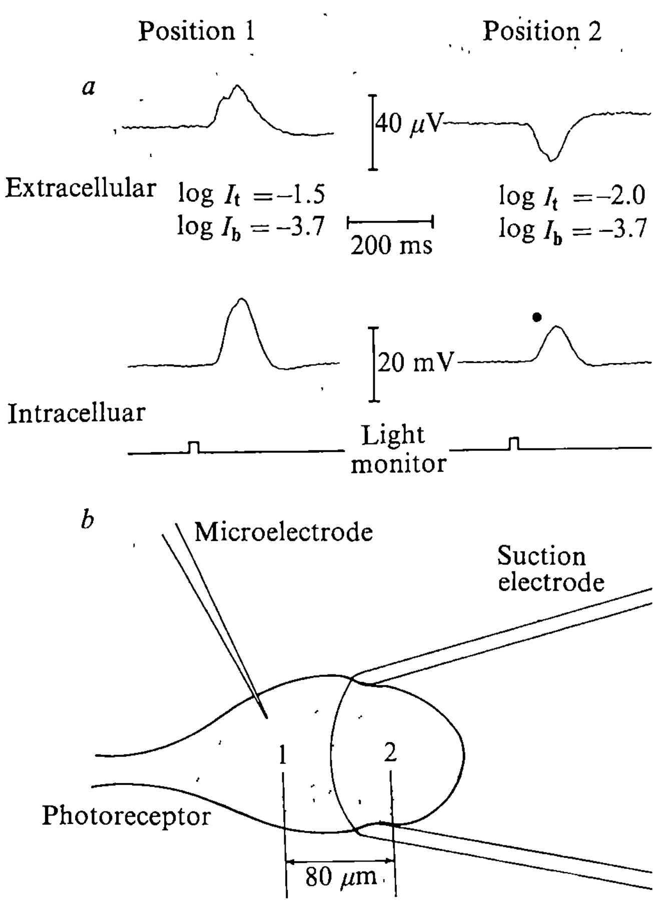

Fig. 1*a*, Local membrane currents produced by local illumination in a light-adapted photoreceptor. *b*, Schematised version of the recording situation, showing the two stimulus spots labelled 1 and 2. Light intensities (I) are given as $\log_{10} I/I_0$ where I_0 is the intensity of the unattenuated beam. I_t is the intensity of the test flash, and I_b is the intensity of the full-field steady background. The extracellular recording was made between a chloride-coated silver wire inside the suction electrode and a chloride-coated silver wire in the bath. An a.c. coupled amplifier with a 0.1-Hz low frequency cutoff was used for the extracellular recording.

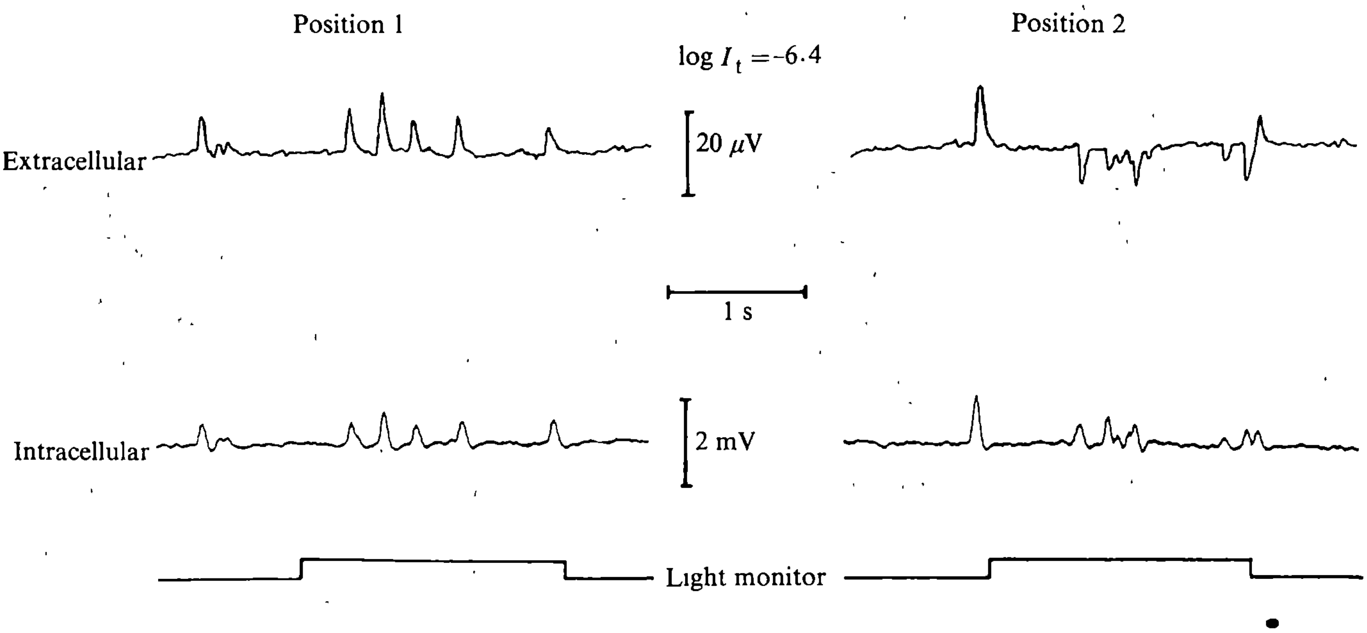
schematic representation of the recording and stimulating situation. The test spot was located at either of two positions, designated 1 and 2. The aim was to stimulate two different regions of the photoreceptor, one inside, the other outside the suction electrode.

Figure 1 indicates that local illumination gives rise to a localised flow of inward membrane current. When the region inside the suction electrode was illuminated (position 2 Fig. 1), a flow of current from the bath into the suction electrode was measured. The path was completed when the current flowed into the illuminated region of the cell, inside the suction electrode, and out of the cell through the unilluminated regions, outside the suction electrode. Similarly, when the photoreceptor was stimulated at a region outside the suction electrode (position 1, Fig. 1*b*) we measured a flow of current from the suction electrode into the bath. As before, the path was completed when the current flowed into the illuminated region of the cell, this time in the region outside the suction electrode, and out of the cell through the unilluminated regions, this time located inside the suction electrode. In both cases the receptor current depolarised the cell, which was shown by the intracellular recordings of the receptor transmembrane potential. These results indicate that localised illumination of these photoreceptors leads to a flow of local membrane current. This finding is similar to the observation of local membrane currents in the outer segment of squid photoreceptors[9]. The observations on squid photoreceptors, however, did not indicate which changes might bring about the local membrane current. As mentioned previously, the voltage clamp technique has shown that illumination initiates a flow of inward membrane current in *Limulus* ventral photoreceptors, that is brought about by an increase in conductance. Our results therefore indicate that a localised conductance increase gives rise to the local inward membrane current, produced by the localised illumination.

When dark-adapted *Limulus* photoreceptors are stimulated with dim flashes, discrete waves of depolarisation (Fig. 2), sometimes referred to as 'quantum bumps', are observed. These 'quantum bumps' have been observed in a variety of arthropod photoreceptors[7,10–13], and in ventral photoreceptors they seem

Fig. 2 Local membrane currents associated with 'quantum bumps' in a dark-adapted photoreceptor. Positions 1 and 2 are the same as those shown in Fig 1*b*. The recording situation was the same as that shown in Fig. 1, but the data shown are from a different cell than in Fig. 1. I_t is the intensity of the test flash. Note what seems to be 'spontaneous quantum bumps' preceding the light stimuli. The above records show only one polarity of these 'spontaneous quantum bumps'. In other records, not presented here, we have also observed 'spontaneous quantum bumps' of opposite polarity. These 'quantum bumps' seem to be spontaneous but we cannot rule out the possibility that they are produced by stray light.



to be produced when a photon excites a single rhodopsin molecule[14]. It has been proposed[15] that the receptor potential is the summation of these quantum bumps. Figure 2 shows that the individual quantum bumps are associated with local membrane currents. The results presented in Fig. 2 indicate that when a single photon excites one rhodopsin molecule, this process initiates a localised conductance increase which, in turn, generates a flow of local membrane current. We suggest that either the localised light-induced conductance increase, or the local membrane current which it generates, or possibly both, are somehow involved in the local adaptation that follows local illumination.

These results can also be interpreted in conjunction with the Ca^{2+} hypothesis of Lisman and Brown[16]. They suggested that a light-induced increase in intracellular Ca^{2+} concentration (Ca_i^{2+}) is a factor controlling light adaptation in *Limulus* ventral photoreceptors. It would seem that following local illumination, the light induced conductance increase and/or the inward current that it initiates, leads to a local rise in Ca_i^{2+} and thereby to local adaptation. This interpretation is supported by the findings of Fein and Lisman[17], who showed that injection of calcium ions into ventral photoreceptors locally desensitised the photoreceptor.

Intracellular Ca modulates sensitivity and time scale in *Limulus* ventral photoreceptors

IN a photoreceptor cell, light induces a change in membrane voltage (the 'receptor potential') The sensitivity of the photoreceptor (defined as the amplitude of the receptor response per unit of stimulus energy) depends on its history of illumination. After a cell has been stimulated by light, its sensitivity becomes reduced (that is, the cell becomes 'light adapted'). Fuortes and Hodgkin[1] reported that previous illuminations not only reduced the sensitivity of photoreceptors in *Limulus* lateral eye but also decreased the latency of the responses to subsequent stimuli. They found that the reduction in latency (referred to as a shortened 'time scale') was greater with brighter adapting lights, and that the shortening of the time scale was much smaller proportionally than was the reduction in sensitivity. Similar changes in time scale also have been found in *Limulus* ventral photoreceptors[2,3].

It has been proposed that a light-induced increase of intracellular free calcium concentration, Ca_i, normally modulates the sensitivity of *Limulus* ventral photoreceptors[4]. The evidence for this proposal is: (1) intracellular injections of calcium ions decrease the amplitude of the receptor potentials[4]; (2) intracellular injection of a calcium buffer tends to prevent light-induced changes in sensitivity[5]; and (3) a light-induced rise of Ca_i has been detected directly with the photoprotein aequorin[6]. Here we show that iontophoretic injection of Ca into *Limulus* ventral photoreceptors not only decreases the sensitivity but also shortens the time scale.

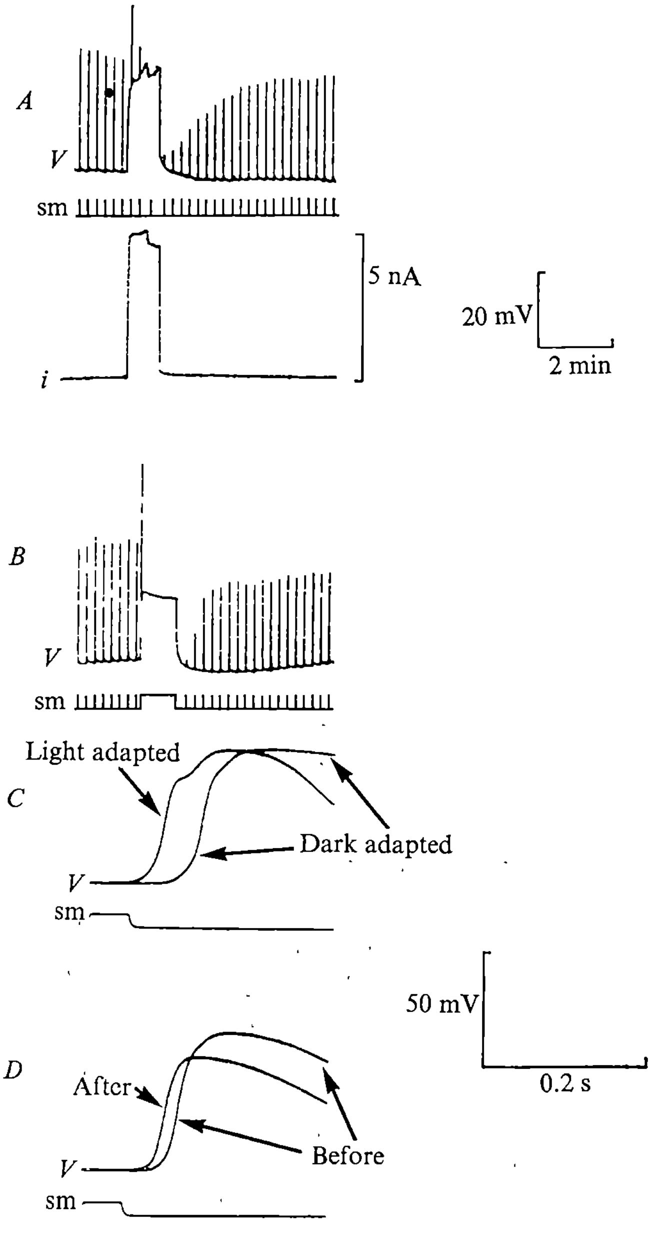

Fig. 1 The amplitude and latency of receptor potentials recorded from *Limulus* ventral photoreceptors, altered by bright lights or by intracellular injection of calcium. *V*, Voltage; sm, monitor of the time of occurrence of stimulus light. A micropipette filled with 3 M KCl was used to measure membrane voltage; a second micropipette filled with 0 09 M CaOH, 0.1 M EGTA and 0.1 M Tris base was used to pass Ca iontophoretically into the cell (refs 4 and 11). Unattenuated stimulus beam was 5×10^{-3} W cm^{-2} on the preparation. *A*, Responses to repetitive brief (20 ms) test flashes (stimulus beam attenuated by 3.9 neutral density) before and after the iontophoretic injection of Ca_i monitor of the current through the electrode containing Ca. *B*, Responses to repetitive brief (20 ms) test flashes (attenuation = 4.8 neutral density) before and after a prolonged adapting stimulus. After the adapting light, the responses to test flashes gradually recovered. Same cell as *A*. *C*, In another cell, the response to a flash (attenuation = 3 6 neutral density) before (dark adapted for 15 min) and 10 s after an unattenuated adapting stimulus. *D*, Same cell as *C*. The response to a flash (attenuation = 3.6 neutral density) before and 10 s after iontophoretic injection of Ca. The cell had been dark adapted for 15 min before each flash.

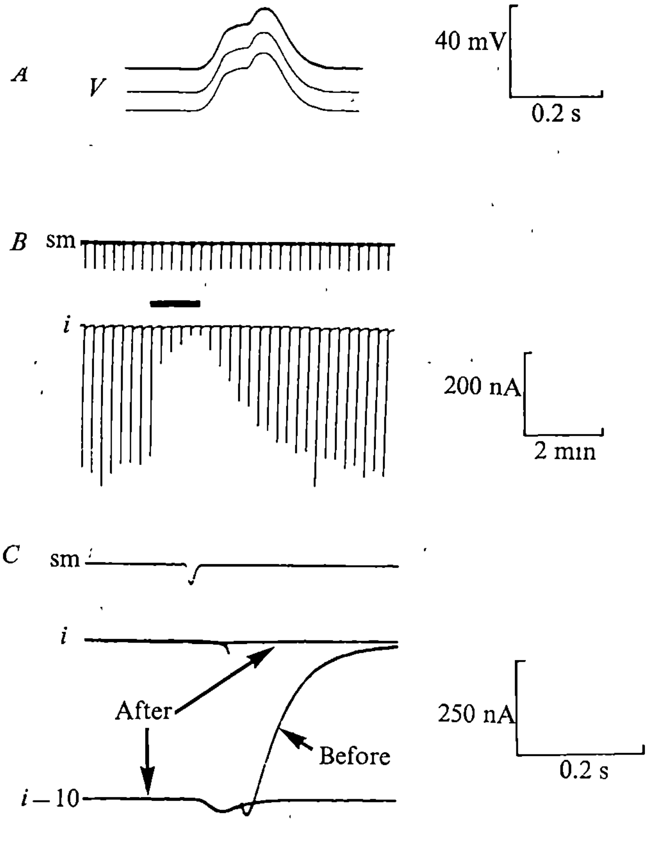
As described previously[4], receptor potentials elicited by brief repetitive flashes are attenuated during the iontophoretic injection of Ca, and recover gradually after the injection (Fig. 1*A*). This phenomenon qualitatively mimics the desensitisation of the cell by an adapting light and the subsequent recovery of sensitivity (Fig. 1*B*).

It has been inferred[4] that the attenuation of the receptor potential by intracellular injection of calcium ions is probably due to the attenuation of the light-induced conductance. To examine directly the effects of injection of calcium ions on the light-induced conductance, cells were voltage clamped during the injection. A cell was impaled with two electrodes filled with KCl, for the voltage clamp, and also impaled with a third electrode for injecting calcium ions iontophoretically. The voltage clamp supplied a current equal and opposite to the current passed out of the Ca-containing electrode; if the inside of the cell was equipotential, no net current would cross the cell membrane due to Ca iontophoresis. Before a cell was voltage clamped, the voltages (receptor potentials and resting voltage) recorded by all three electrodes were found to be nearly identical (Fig. 2*A*). The cell was then voltage clamped, and the currents induced by brief dim repetitive flashes were measured. During the iontophoretic injection of Ca the light-induced current became progressively smaller, and after the injection it progressively recovered (Fig. 2*B*). The intensity of the repetitive flashes was chosen to be within the linear portion of the relationship between flash intensity and peak light-induced current; therefore, the reduction in light-induced current was directly proportional to the reduction in the sensitivity of the cell. Thus, the direct intracellular injection of Ca caused a reduction of the sensitivity of the photoreceptor, in the absence of a change of membrane voltage. We have also found that intracellular iontophoretic injection of calcium ions does not noticeably change the reversal voltage of the current induced by a brief flash Thus, with membrane voltage held constant, the light-induced current is directly proportional to the light-induced conductance. We conclude that the finding illustrated in Fig. 2*B* directly demonstrates that an increase of intracellular free calcium modulates the light-induced change in membrane conductance which underlies the photoreceptor response. It has been similarly demonstrated that bright illumination reduces the conductance increase evoked by subsequent stimuli[7].

Fig. 2 A cell was impaled with two KCl-filled microelectrodes and a third electrode containing Ca solution. The unattenuated stimulus light was 5×10^{-3} W cm^{-2}. *A*, From the dark-adapted cell the three electrodes recorded identical receptor potentials to a brief flash (attenuation = 4.8 neutral density). *B*, Current (*i*) induced by repetitive 50-ms test flashes (attenuation = 4.2 neutral density; sm, stimulus monitor) before, during, and after iontophoretic injection of Ca. Duration of injection indicated by bar. Holding voltage equal to dark resting voltage. The injection caused no change in the membrane current measured in the dark (between flashes). *C*, Current (*i*) induced by test flashes (attenuation = 3.0 neutral density) before and after iontophoretic injection of Ca while cell was voltage clamped at dark, resting voltage. Response after injection is shown at two amplifications, differing by a factor of 10.



Using brief bright stimuli, a dramatic shortening of the time scale of the receptor potential was found after the photoreceptor was light adapted (Fig. 1*C*). To see if an increase of Ca$_i$ affected the time scale in addition to reducing the sensitivity, we measured membrane voltage during and after iontophoretic injection of calcium ions. Shortening of time scale also occurred after the intracellular iontophoretic injection of Ca (Fig. 1*D*). Moreover, the shortening of time scale did not depend on passing net current across the cell membrane during the iontophoretic injection; injection of Ca while the cell was voltage clamped shortened the time scale (Fig. 2*C*) and also decreased the sensitivity. Thus, increasing intracellular free calcium mimics two effects of previous illumination: a large reduction of sensitivity and a proportionally smaller shortening of the time scale. Injection of calcium ions does not, however, mimic the excitatory effect of light. Figure 2 shows that membrane current in the dark (measured at resting voltage) was not affected by the injection. This clearly shows that, in *Limulus*, a rise of Ca$_i$ is not the signal for excitation, as has been proposed for vertebrate photoreceptors[8,9].

In summary, we have found that in ventral photoreceptors, changing a single quantity, the free intracellular calcium, leads to both a shortening of time scale and a reduction of sensitivity. Increasing calcium concentration has been found to attenuate stimulus-induced changes of membrane conductance channels in other membranes (compare 'stabilisation' effects of Ca; ref. 10). Our findings that intracellular injection of Ca not only decreases the sensitivity but also shortens time scale of the light-induced current suggests that the action of Ca$_i$ is probably not a nonspecific effect on the conductance channels. These findings further support the hypothesis that a change of Ca$_i$ specifically participates in the physiology of light adaptation in *Limulus* ventral photoreceptors.

Selective release of newly synthesised and newly captured GABA from synaptosomes by potassium depolarisation

NORADRENALINE and acetylcholine synthesised *de novo* are released in preference to the endogenous store following nerve depolarisation. Kopin *et al.*[1] showed that the specific activity of noradrenaline (^{14}C-tyrosine precursor) released from cat spleen during sympathetic nerve stimulation is greater than that of the tissue store; however, ^{3}H-noradrenaline which was just taken up by the nerve is released concomitantly with the endogenous store. In similar experiments, newly synthesised acetylcholine is selectively released from superior cervical ganglia[2], phrenic nerve[3], *Torpedo* electroplax[4], and brain cortical slices[5]. We used rat cortical synaptosomes (pinched off nerve endings) to study the temporal relationships of GABA biosynthesis, uptake and release.

Suspensions, enriched in synaptosomes, prepared by standard subcellular fractionation techniques, take up alleged neurotransmitter substances (for example, γ-aminobutyric acid (GABA), L-glutamate, L-aspartate) against a concentration gradient by specific sodium-dependent high affinity (low K_m) transport systems[6]. These high affinity transport systems are thought to be important in inactivating neurotransmitter action. Following electrical stimulation[7] or calcium-dependent potassium depolarisation[8,9], preparations enriched in synaptosomes specifically release neurophysiologically active amino acids (GABA, L-glutamate, L-asparatate). Using ^{14}C-L-glutamate as a precursor to measure GABA biosynthesis *de novo* and low concentrations of ^{3}H-GABA as a substrate for the high affinity uptake system, we find that newly synthesised GABA is released from synaptosomes concomitantly with the GABA taken up by the high affinity transport system. Moreover, both newly synthesised and captured GABA are released in preference to endogenous GABA stores.

GABA is a probable transmitter in the vertebrate central nervous system[10] and the established neurotransmitter at the crustacean neuromuscular junction[11]. Although usually considered an inhibitory neurotransmitter, we suggested that GABA may be the excitatory transmitter of the olfactory nerve in the gar fish and pike[12]. Glutamate decarboxylase catalyses the biosynthesis of GABA according to

$$\text{L-glutamate} \rightarrow \text{GABA} + CO_2$$

This enzyme, which requires pyridoxal phosphate[13], is strongly inhibited by carbonyl-trapping reagents such as hydroxylamine and hydrazine[14], and also by mercaptosuccinate (our unpublished observations).

Using male Sprague–Dawley rats (200–250 g), fractions enriched in synaptosomes were isolated from crude mitochondrial suspensions on discontinuous Ficoll gradients[15] and stored at 0 °C in calcium-free Ringer[9] containing 20 mM morpholinopropane sulphonic acid (pH 7.4). All incubations were completed within 7 h after the animals were killed. To remove ^{14}C-GABA and other impurities, commercial ^{14}C-(U)-L-glutamate (237 Ci mol^{-1}) was subjected to paper electrophoresis in 8% acetic acid–2% formic acid. Commercial ^{3}H-GABA (36.7 Ci mmol^{-1}) was free from impurities using this system. Preparations enriched in synaptosomes always contain adventitious microsomes and myelin. Control studies which we report show that the conclusions are unaltered by this contamination.

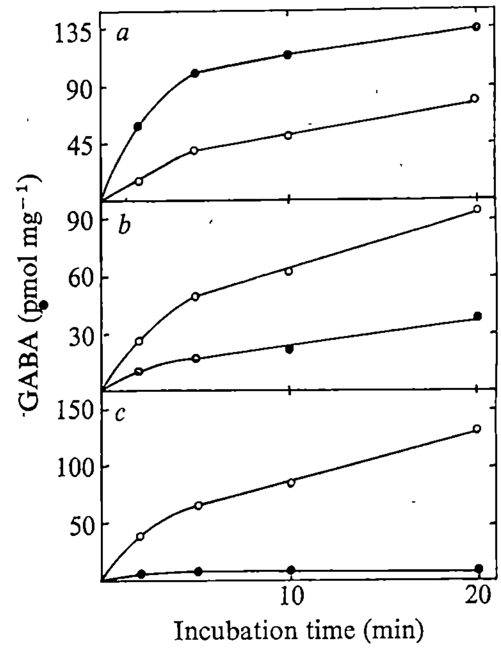

Fig. 1 Variation of newly synthesised and newly captured GABA in synaptosomes by changing exogenous substrate concentrations. A 90-µl aliquot of synaptosomal suspension (50–60 µg protein) was incubated at 25 °C for the time indicated with 10 µl of solution containing ^{14}C-L-glutamate and ^{3}H-GABA in Ringer's solution to give the following final respective concentrations: *a*, 30 µM–0.6 µM; *b*, 30 µM–0.3 µM; *c*, 30 µM–0.05 µM. Synaptosomes were collected on Millipore filters (0.45-µM pore). The filters were placed on Whatman 3MM paper and electrophoresed in 8% acetic acid–2% formic acid at 30 V cm^{-1}. After drying, carrier GABA was visualised with ninhydrin and quantitatively analysed for newly synthesised (^{14}C) (○) and newly captured (^{3}H) (●) GABA in Tritosol[18] using the channel ratios method[19]. Results are expressed per mg synaptosomal protein. In the conditions used, tritiated GABA was 17,000 c.p.m. pmol^{-1} and ^{14}C-GABA (newly synthesised) was 94 c.p.m. pmol^{-1}. Similar results were obtained in 2–4 independent experiments.

After incubating synaptosome fractions with ^{14}C-L-glutamate (30 µM) and ^{3}H-GABA (0.6 µM) at 25 °C, the rate of accumulation of both radiolabels into synaptosomes isolated by Millipore filtration is linear for 4 min and gradually flattens out between 20 and 30 min. To assess the extent of metabolism of these substances, including the conversion of L-glutamate to GABA, the synaptosomal preparation was collected by centrifugation (6,000g, 5 min, 4 °C) after incubation for 30 min with each labelled precursor. Subsequently, a water extract of the synaptosomes was prepared, applied directly on to paper, and electrophoresed. The position of the label was determined with a radiochromatogram scanner and that of the amino acids was determined by the ninhydrin reaction. About 80–90% of the radiolabel comigrated with the precursor. Moreover, L-glutamate (3%) was converted into a substance which comigrated with GABA during paper electrophoresis using 5.5% acetic acid–pyridine (pH 4.2) or the acetic acid–formic acid system. Incubation of the synaptosomes with hydroxylamine (1 mM) or mercaptosuccinate (1 mM) inhibits GABA bioformation from ^{14}C-L-glutamate by 90% and 25%, respectively, as determined after resolving sequestered GABA and L-glutamate by paper electrophoresis. In addition the ratio of newly synthesised GABA (^{14}C-L-glutamate precursor) and newly captured GABA (^{3}H-GABA precursor) varies with the concentration of precursor used in the synaptosomal incubation medium (Fig. 1*a*–*c*). Decreasing the concentration of ^{3}H-GABA in the medium, for example, decreases its uptake into synaptosomes with an attendant increase in the ratio of ^{14}C-GABA (newly synthesised) to ^{3}H-GABA (newly captured).

After documenting the biosynthesis of GABA from

^{14}C-L-glutamate and the uptake of ^{3}H-GABA into the synaptosome preparation, the effect of potassium depolarisation on the release of newly synthesised and captured GABA was studied. Synaptosomes containing ^{14}C- and ^{3}H-GABA release the candidate neurotransmitter on treatment with 56 mM potassium–1 mM calcium (Fig. 2*a–c*) The ratio of newly synthesised to newly captured GABA (labelling ratio) released closely parallels that found intrasynaptosomally before (Fig. 2*a–c*) and after (data not shown) potassium depolarisation In the data shown (Fig. 2*a–c*), the labelling ratios of intrasynaptosomal and released GABA were (*a*) 0.58, (*b*) 2.49; (*c*) 22.8 (±8%). This shows that the GABA released (up to 70%) by potassium depolarisation consists of both newly captured and synthesised substance Although the intrasynaptosomal ratio of these two forms of GABA can be controlled by varying substrate concentrations, neither form is selectively released. These results reflect net release since the magnitude of re-uptake of labelled GABA during depolarisation cannot be estimated.

Next, the specific radioactivity of stored and released GABA was measured. After depolarisation, the material released initially contains newly synthesised (^{14}C) and captured GABA (^{3}H) of higher specific activity than that found in the synaptosomes before potassium–calcium treatment (Table 1). With longer incubations, the specific activity of each label decreases to a value similar to that found in the initial preparation. These results support the hypothesis that newly synthesised and captured GABA are released preferentially when compared with the endogenous GABA store

Since myelin and microsomes sequester GABA[9], experiments were carried out to test the effect of potassium depolarisation on GABA release from these contaminants. Experiments performed with synaptosome preparations demonstrate that part of the sequestered radiolabel sediments with the myelin–microsomal fraction on sucrose density gradients, whereas the major portion comigrates with the synaptosomal fraction[16] Depolarisation of the preparation enriched in synaptosomes substantially reduces label comigrating with the synaptosomal fractions, but fails to release label from the myelin–microsomal fractions. In a control experiment using a myelin–microsomal preparation, depolarisation also fails to release label. These results are consistent with the observations of Levy *et al*, who demonstrated that myelin and microsomal preparations fail to release GABA by potassium treatment[9] Our experiments demonstrate that release of labelled GABA from synaptosome preparations by potassium depolorisation is not adventitious, and confirms the contention that simulus-induced release is synaptosome specific

Table 1 Release of endogenous, newly synthesised and newly captured GABA by depolarisation

Time (s)	Total GABA released (nmol mg^{-1})	Synthesised (pmol per nmol total GABA)	Captured (pmol per nmol total GABA)
2	< 0.25	> 40	> 26
20	0.74	20.1	15.7
80	1.48	14.4	11.8
150	1.78	11.8	9.5

A synaptosome preparation (870 µg protein) was incubated in a final volume of 300 µl of Ringer containing 30 µM ^{14}C-L-glutamate and 0.6 µM ^{3}H-GABA for 20 min at 25 °C. Synaptosomes were collected, washed and depolarised for the time indicated with K^+-Ca^{2+} as described in Fig. 2. Fractions containing released GABA were lyophilised and redissolved in 250 µl of 10 mM acetic acid. Total GABA was measured by the enzymatic fluorimetric procedure of Kravitz and Potter[20]. Newly synthesised (^{14}C) and newly captured (^{3}H) GABA were determined as described in Fig. 2. Intrasynaptosomal levels of GABA (before depolarisation) were: total GABA—8.7 nmol mg^{-1} protein; newly synthesised—12.3 pmol per nmol total GABA; newly captured—8.3 pmol per nmol total GABA. All determinations were performed in triplicate Average values (range±9%) are given.

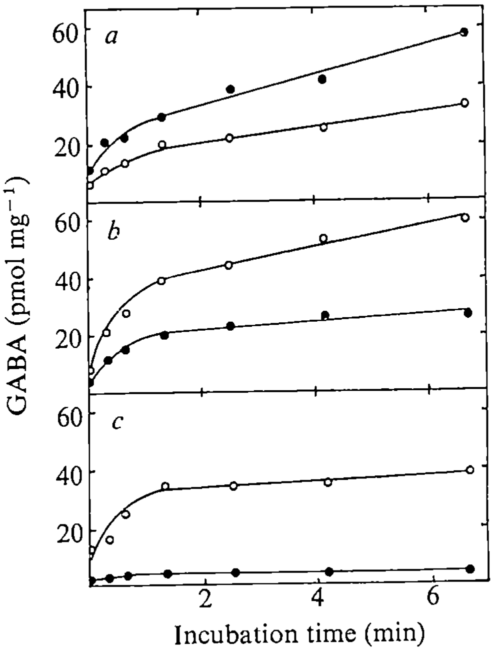

Fig. 2 Release of newly synthesised and newly captured GABA from synaptosomes. Synaptosomes were labelled with ^{14}C- and ^{3}H-precursor as described in Fig. 1*a–c* for 20 min, using 120–130 µg of synaptosomal protein in a final incubation volume of 250 µl. Synaptosomes were collected by centrifugation at 4,500*g* for 3 min and washed twice with 2.5 ml of cold Ringer to remove extrasynaptosomal isotope. The pellet was resuspended in 250 µl of Ringer (on ice); then 250 µl of Ringer containing 112 mM potassium chloride and 2 mM calcium chloride was added rapidly. After incubation at 25 °C for the time indicated, the components released into the medium were resolved from synaptosomes by Millipore filtration. The filtrates were lyophilised and redissolved in 100 mM acetic acid containing carrier GABA. Aliquots were electrophoresed on Whatman 3MM paper for 90 min in 5.5% acetic acid–pyridine, *p*H 4.2 at 15 V cm^{-1}. After drying, GABA was quantitatively analysed as described in Fig. 1. In the conditions used, the following concentrations (pmol mg^{-1}) of newly synthesised and newly captured GABA (respectively) were present before potassium depolarisation (see Fig. 1*a–c*): *a*, 80–137; *b*, 97–39; *c*, 130–5.7. ○, Newly synthesised, ●, newly captured. Similar results were obtained in 2–4 independent experiments.

A 30-µM concentration of L-glutamate is an effective precursor of GABA in the synaptosome preparation. The K_m of the glutamate high affinity uptake system, the process presumed to inactivate the action of this excitatory neurotransmitter candidate, is about 20 µM (ref 17). Whether glutamate transport into neurones using GABA as the neurotransmitter is mediated by a similar high affinity transport system remains to be clarified. Newly captured and newly synthesised GABA are released in ratios similar to those found in synaptosomes before depolarisation. Release of GABA is thus unlike that of noradrenaline in the peripheral sympathetic nervous system (splenic nerve) of cat, where the newly synthesised transmitter is released in preference to that which is newly captured. Based on our experiments with rat cortical synaptosomes, GABA reuptake is not only important for terminating transmitter action, but seems to serve as a rather direct source for release of GABA in subsequent nerve volleys.

Purified hormones from the crustacean eyestalk and their physiological specificity

THE amino acid compositions of two peptide hormones, both acting on the pigmentary-effector system of crustaceans, have been reported[1]. One of these, erythrophore concentrating hormone (ECH) has a major function in the rapid physiological colour changes of crustaceans, by concentrating pigment granules of the erythrophores, and is the first crustacean eyestalk hormone described[2]. The second eyestalk hormone, discovered not long afterwards[3], moves the distal (DRP) and reflecting retinal pigments of dark-adapted *Palaemonetes* and *Palaemon* into the light-adapted position, but purified hormone has so far been tested on only the DRP. A third well characterised hormone, hyperglycaemic hormone (HGH), increases glucose concentration of the blood, but such hyperglycaemic responses may vary in cross tests among crustacean species[4–6]. The amino acid composition of HGH has been determined. A summary of six analyses of five different preparations of HGH from eyestalks of *Cancer magister* is shown in Table 1; specific analyses for tryptophan have not been made. Details of the separation and purification will be reported elsewhere.

The diversity of physiological responses produced by hormones from the crustacean eyestalk[7–9] raises the question of the number of different hormones involved, that is, is each type of response produced by a single hormone, or may one hormone be responsible for more than one effect?

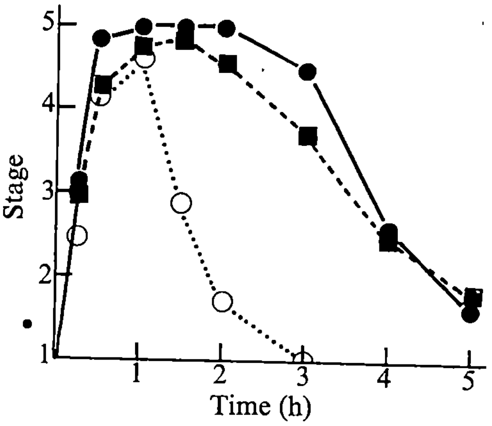

Fig. 1 Effects of synthetic light-adapting DRPH on chromatophores of *U. pugilator*. ●, Melanophores (10 animals); ■, erythrophores (10 animals); ○, leukophores (20 animals). Both eyestalks were removed from male crabs, average wet weight, 3.8 g (range 3.5–4.2 g) 18 h before testing to ensure that, at injection, melanophores and erythrophores were in stage 1. Normal males, averaging 1.6 g wet weight (range 1.4–2.1 g), were adapted to illuminated black backgrounds in individual fingerbowls so that the leukophore pigment was fully concentrated; after injection they were kept in the black containers except during the short intervals for observing the leukophore stage. The large individuals were injected with 0.2 μg and the small ones 0.1 μg of synthetic hormone (105 μg dissolved in 1.0 ml Pantin's saline[15] containing 1 μl of thiodiethanol). The hormone was stored at −20 °C between injections of groups of crabs. Chromatophore stages were read at ×36–×54 magnification.

The ideal approach is to test the specificity of response to pure hormone.

ECH has been tested for its physiological specificity on three crustacean species. Doses of 10^{-8} g of synthetic ECH concentrated the erythrophore pigments in *Uca pugilator* and in *Cambarellus shufeldti*, but were without effect on leukophores and melanophores of these species[10]. On the other hand, synthetic ECH in doses of 5×10^{-11} g, as well as hormone purified from eyestalks of *Pandalus borealis*, concentrated pigment both in leukophores and erythrophores of *Palaemon adspersus*[11] without eyestalks. The maximum leukophore response was small, an average stage 2.5 (on the Hogben and Slome[12] scale of 1–5) being reached 6 min after injection, with pigment fully dispersed again after the next 25 min. Although control injections are not described and leukophore responses to a range of doses of synthetic ECH are not reported, the results indicate differences in specificity of response to this hormone among crustacean species.

Table 1 Amino acid composition of hyperglycaemic hormone (HGH) from eyestalks of *C. magister*

Amino acid	Residues in samples 140–1	142–3	144–5	146–7C	146–7D	148–9A	Average number of residues	Range used	Estimated round number of residues

*Cysteine, methionine and to some extent isoleucine are always low; also tryptophan if present.
†Valine not increased by 70-h hydrolysis time.
‡Values not used in averaging number of residues.

During purification studies on light-adapting DRPH[13,14], successive chromatography of eyestalk extract on columns of Sephadex G-25, DEAE–cellulose, and CM–cellulose revealed molecular polymorphism of the hormone. Each molecular version, in addition to light-adapting DRP, also dispersed pigments in melanophores, erythrophores and leukophores of *U. pugilator*. Such persistent association of physiological responses by the four pigmentary effectors indicated the likelihood of molecular identity between light-adapting DRPH and dispersers of chromatophoral pigments.

This possibility was tested with synthetic light-adapting DRPH on *Uca* (Fig 1). Pigment became dispersed in the three types of chromatophores, the maximum response occurring 30–60 min after hormone injection. Leukophores seem to be less sensitive to the hormone than melanophores and erythrophores. Doses of 2 ng produced an average stage 3.8 for melanophores in 6 eyestalkless *Uca* by 30 min after injection (not shown); the melanophores had returned to stage 1 after 3 h. Control injections of saline–thiodiethanol were without effect on the three kinds of chromatophores; five control animals were used for each chromatophore type.

The results show that light-adapting DRPH is also a disperser of chromatophoral pigments in *Uca*, and that a single hormone may elicit more than one physiological response. The role of purified HGH in the reported activation of phosphorylase and inhibition of uridine-diphosphate-glucose glycogen transglucosylase by eyestalk hormone[16,18] will be investigated.

Professor Rainer Keller, Drs Klaus-Dieter Spindler and Margaret Spindler-Barth were coworkers in the purification of HGH from *C. magister;* amino acid analyses of this HGH were done by Dr B. Brimhall (University of Oregon Medical School). Dr Per Fernlund provided a sample of synthetic light-adapting DRPH. Grants from the National Institutes of Health and from the National Science Foundation supported this research.

Immunological cross reactivity between testicular androgen-binding protein and serum testosterone-binding globulin

WE have reported the presence of a testicular androgen-binding protein (ABP) which is secreted into the testicular fluid of several mammalian species[1]. ABP is produced by the Sertoli cells and is specifically stimulated by follicle stimulating hormone (FSH)[1–7] It is found in particularly high concentrations (3×10^{-7} M) in the efferent duct fluid of rabbits.

Rabbit serum also contains an androgen-binding protein (TeBG) with properties very similar to ABP[8–11]. In rabbits, ABP and TeBG are indistinguishable by size, stability and steroid-binding properties[12] (Table 1). To compare ABP and TeBG further, we have used antisera raised against purified ABP to investigate whether or not ABP and TeBG show immunological cross reactivity.

ABP was purified from 3,000 epididymides of adult rabbits by ammonium sulphate precipitation, ion exchange chromatography on DEAE–cellulose, gel filtration on Sephadex G-200, hydroxylapatite chromatography and preparative polyacrylamide gel electrophoresis[13]. In the purified preparation there was a thousandfold increase in specific ABP-binding activity compared with that of the 105,000*g* supernatant Purified (200 μg) or partially purified ABP (12 mg) was injected into young female guinea pigs after emulsification in 0.5 ml of Freund's complete adjuvant The animals were bled after 6 weeks and those showing an ABP titre were given booster injections to increase the titre. Antisera were checked for precipitin lines by double diffusion tests in agar[14]; and by inhibition of ABP-binding activity as measured by steady-state polyacrylamide gel electrophoresis[15].

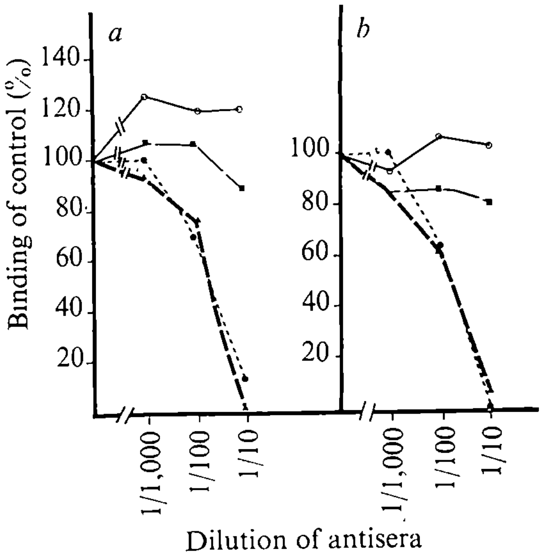

Fig. 1 Inhibition of ^{3}H-DHT binding to ABP (*a*) and TeBG (*b*) by different dilutions of anti-ABP antisera. Four guinea pigs were injected with partially purified rabbit ABP in Freund's complete adjuvant, and bled after 6 weeks. Various dilutions of antiserum (1/10, 1/100, 1/1,000) were added to an equal volume of partially purified ABP or immature rabbit serum (diluted 1:50, v/v). Normal guinea pig serum in the same dilution served as controls. After incubation for 48 h at 2–4 °C the samples were centrifuged at 10,000*g* for 15 min and binding of ^{3}H-DHT to ABP and TeBG was analysed by steady-state polyacrylamide gel electrophoresis[15]. There was no visible precipitation at any dilution of antisera ○, AS1; ●, AS2; ■, AS3; ▲, AS4.

As Fig. 1*a* shows, antisera from animals 2 and 4 caused 100% inhibition of ABP-binding activity at a dilution of 1 : 10. Some inhibition was also observed at a dilution of 1 : 100 but none at 1 : 1,000. Antisera from animals 1 and 3 showed little or no inhibition of steroid-binding activity, although they had activities against other antigens in the partially purified ABP preparation, as demonstrated by double diffusion tests in agar. Figure 1*b* shows that antisera raised in animals 2 and 4 also inhibited binding of ^{3}H-DHT to TeBG, and inhibition at different dilutions of antisera was identical to that of the inhibition of ABP-binding activity The finding that all four antisera showed precipitin lines in double diffusion tests in agar, and only two had a detectable titre against ABP and TeBG suggested that the inhibition was caused by specific antibody to ABP and TeBG and not by an artefact due to coprecipitation with contaminating antigens.

Table 1 Physicochemical properties of rabbit ABP and TeBG

	ABP	TeBG
$S_{20,w}$	4.7S (12) 4.5S (13)	4.4S (12)
Stokes radius (r_s)	43 Å (12)	44 Å (12)
Molecular weight ($S_{20,w}$, r_s)	74,000 (12)	76,000 (12)
Molecular radius (PAGE)	2.74 nm (12)	2.74 nm (12)
f/*fo* (molecular weight, r_s)	1.61 (12)	1.55 (12)
Molecular weight (PAGE)	75,000 (12)	75,000 (12)
Molecular weight (SDS–PAGE)	68,000 (13)	
Molecular weight (equilibrium ultracentrifugation)	65,500 (13)	
*p*I	4.7 (12, 13)	5.4 (12)
Ka^{DHT} at 0 °C	1.6×10^9 M^{-1} (12)	1.9×10^9 M^{-1} (12)
Steroid specificity	DHT > adiol > testosterone > progesterone > androstenedione > cortisol (12)	
Stability		
Binding destroyed by heat	> 50 °C (12)	> 50 °C (12)
Dissociation rate DHT–ABP complex ($t_{1/2}$ at 0 °C)	6 min*	5.2 min (11)

(v = 0.70 cm^3 g^{-1}). PAGE, polyacrylamide gel electrophoresis; SDS–PAGE, PAGE in 0.1% sodium dodecyl sulphate; *p*I, isoelectric focusing; *f*/*fo*, frictional ratio. DHT, dihydrotestosterone; adiol, 5α-androstane–3α,17β-diol. References are given in parentheses.
*Our unpublished results.

One explanation for the apparent immunological similarity between ABP and TeBG could be that TeBG is one of the proteins contaminating the ABP preparations used for immunisation, and that antibodies to both ABP and TeBG had been developed. To examine this possibility, more guinea pigs were immunised and antisera from different animals and bleedings were tested for inhibition of steroid binding to ABP and TeBG. As Fig. 2 shows, all antisera that inhibited steroid binding to ABP also inhibited binding to TeBG A plot of the binding to ABP against the binding to TeBG gave a positive correlation of 0.985. This high correlation between inhibition of steroid binding to ABP and TeBG strongly indicates that binding to both proteins is inhibited by the same antibody, and not by the products of different immune responses.

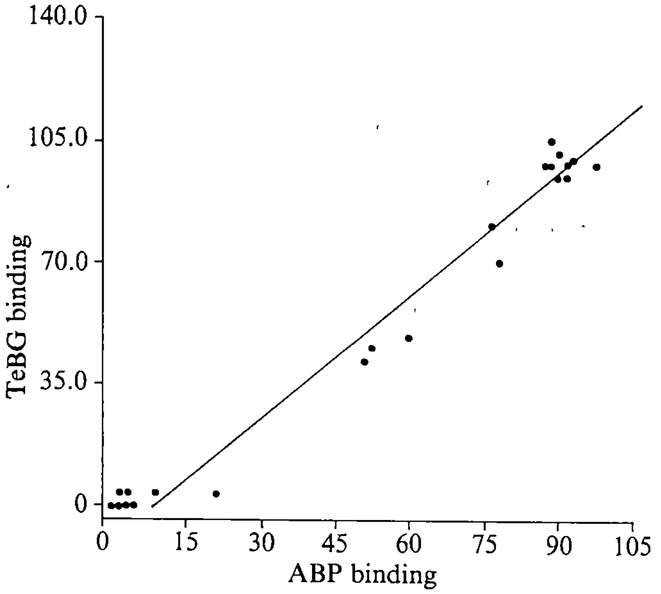

Fig. 2 Effect of 22 different antisera on ^{3}H-DHT binding to ABP (abcissa) and TeBG (ordinate). Antisera diluted 1:50 (v/v) were added to an equal volume of diluted rete testis fluid (1:20, v/v) or immature rabbit serum (dilution 1:20, v/v). Normal guinea pig serum served as control. After incubation for 48 h at 2–4 °C, the samples were centrifuged at 10,000*g* for 15 min and binding of ^{3}H-DHT to ABP and TeBG measured by steady-state polyacrylamide gel electrophoresis[15]. No visible precipitation was seen with any of the antisera used. Nine antisera caused no inhibition of ABP and TeBG binding Six antisera inhibited completely binding both ABP and TeBG. Seven antisera caused partial inhibition of both ABP and TeBG. Correlation coefficient for regression line = +0.985.

Thus, the present study shows that ABP and TeBG, in addition to having very similar physicochemical properties also show similar if not identical antigenicity ABP is produced in the Sertoli cells and secreted into testicular fluid while TeBG is present in the systemic circulation but of unknown origin. It is not likely that ABP originates in serum since proteins of this size cannot penetrate the blood–testis barrier[16]. ABP is also found in high concentrations in the rat, which lacks serum TeBG. Furthermore, Sertoli cells in culture release ABP into the medium and this process is stimulated by FSH[17,18]. It is also unlikely that TeBG originates in the testis, since high concentrations of TeBG are found in orchiectomised males as well as normal females[8–11]. Furthermore, ABP production is stimulated by FSH and androgens, while TeBG concentrations in serum are depressed by androgens and increased by oestrogens. Thus, ABP and TeBG might well be the same protein but produced at two different sites in the body and regulated by different hormonal mechanisms. Recent studies indicate possible differences in the carbohydrate portions of the ABP and TeBG molecules. TeBG is firmly bound by concanavalin A, while there is little or no binding of ABP (S C.W. *et al.*, unpublished) These studies suggest minor differences in the terminal sugars of the two proteins; and chemical analysis of purified preparations will be required to establish these differences further.

DNA replication and accelerated chain growth in oestrogen-stimulated uterine cells

OESTROGEN has been shown to reduce S phase duration in uterine epithelial cells, although no agreement has been reached either on the exact values of cell cycle parameters, or even on the relative magnitude of the hormone-induced modifications[1-6]. It has also been shown that eukaryotic DNA molecules consist of replicative units arranged end-to-end, from the middle of which DNA synthesis proceeds bidirectionally at divergent fork growing points until fusion occurs with adjacent sections. The chain growth rate as well as the mean distance between initiation points were found to be specific for each cell type[7-13]. From this it can be inferred that oestrogen-dependent shortening of S phase in the uterine epithelium is due to speeding-up of replication along pre-existing units, or to multiplication of simultaneously operating replicative sections, or to both these mechanisms. The results that we have obtained from autoradiography of DNA fibres confirm that oestrogen increases the rate of DNA fork replication.

The microscopic measurements of grain tracks corresponding to replicated sections of DNA double helices show that with both ^{3}H-TdR pulse durations uterine epithelial DNA from oestradiol-treated mice contains labelled segments which are 50% longer than in controls (Figs 1 and 2). On the other hand, distances between centres of adjacent grain tracks do not seem to vary. Only in the experimental group given a 60-min labelling pulse were the values apparently somewhat higher. Although the comparison between experimental and control data is meaningful in terms of modifications of replication rate and density of replicative units, the calculation of true fork growth rate and initiation intervals from our data presents some difficulties which have already been partly discussed[12,13]. The histograms of track lengths are, in fact, an indeterminate mixture (see Fig. 3) of: (1) short sections arising from unidirectional replication of half-replicative units in which DNA synthesis was already under way at the start of pulse labelling; (2) labelled sections of short to medium length corresponding to bidirectional chain growth in units initiated at different times in the pulse periods; (3) average to long tracks due to fusion of adjacent replicons.

Frequencies of short tracks are probably overestimated since such segments are more often scored in the numerous short internal autoradiograms available for measurement. Being more prone to be broken or blurred by superposition with other fibres, suitable long tandem arrays are less often found. Consequently, fork replication rate, derived from halving the modal length of labelled segments is bound to be too low. For similar reasons centre–centre distances do not represent the true value of intervals between initiation points. Measurements involving fused sections tend to overestimate the interval length whereas those performed between partly labelled halves of the same replicon will strongly underrate it. Moreover, if two neighbouring initiation points are far apart they will be less often identified as parts of the same fibre[11]. Therefore, although on a relative basis, centre–centre measurements do reflect the density of replicative units along DNA molecules, in absolute terms they are likely to provide a gross exaggeration of this parameter

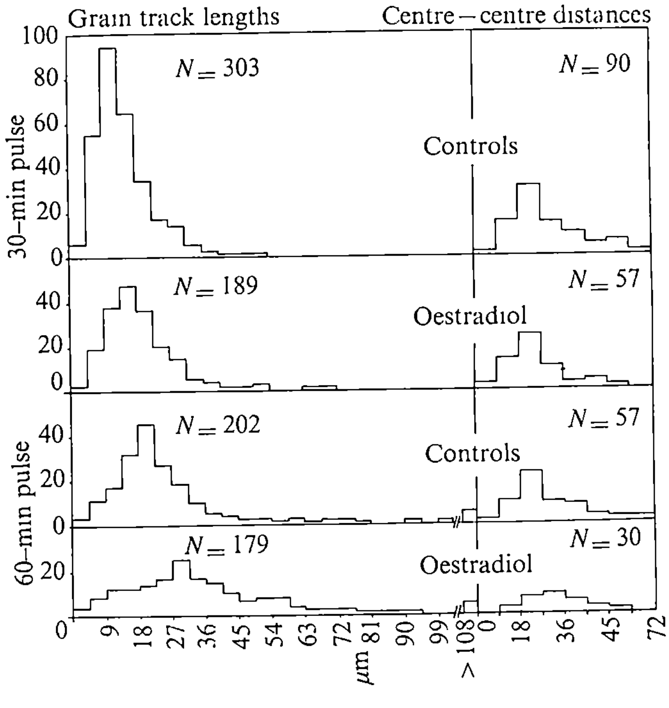

Fig. 1 Effect of oestradiol on lengths and distances between centres of ^{3}H-TdR labelled segments in DNA molecules isolated from mice uterine epithelial cells. One week after ovariectomy, albino mice were grouped into 10 experimental and 14 control animals which were injected intraperitoneally with 100 ng 17 β-oestradiol in 100 μl propylene glycol, respectively, or with the same volume of vehicle solvent alone. After 15 h oestrogen action the uterine horns were dissected out, split longitudinally and transferred into TC medium Eagle Earle BSS (Difco) at 929 mg % in water, neutralised at *p*H 7 3 by 5% $NaHCO_3$ and supplemented with calf serum (10 ml per 100 ml of initial solution). A first incubation period of 30 min at 37 °C was effected in the presence of 2×10^{-6} M 5-fluorodeoxyuridine (FUdR) only, to enable optimal DNA labelling[14]. Thereafter the uteri were pulse-labelled in the same medium containing FUdR but supplemented with ^{3}H-thymidine (^{3}H-TdR) of high specific activity (52 Ci mM^{-1}) at a final concentration of 5×10^{-6} M In each group half of the uterine horns were removed and washed after 30 min whereas the remaining material was incubated with the isotope for 60 min After termination of the ^{3}H-TdR pulse, uterine epithelial nuclei were isolated as described by Smith *et al.*[15] The nuclear pellets were resuspended in 0.3 ml of phosphate buffered saline (*p*H 7.4) and were used to perform DNA fibre smears according to the method of Lark *et al.*[16]. These smears were processed for autoradiography by dipping in 50% diluted Ilford K5 emulsion and were developed in 50% Dektol (Kodak) after 17 weeks' exposure. Measurements were performed with a micrometric scale only on internal autoradiograms to avoid broken DNA sections (that is by disregarding both end segments of tandem arrays on which measurements were effected) Statistical comparison was performed by use of Wilcoxon's rank test. With both pulse durations the increment of track lengths due to oestradiol was highly significant ($P<0.001$) whereas there was no significant difference between distributions of centre–centre distances.

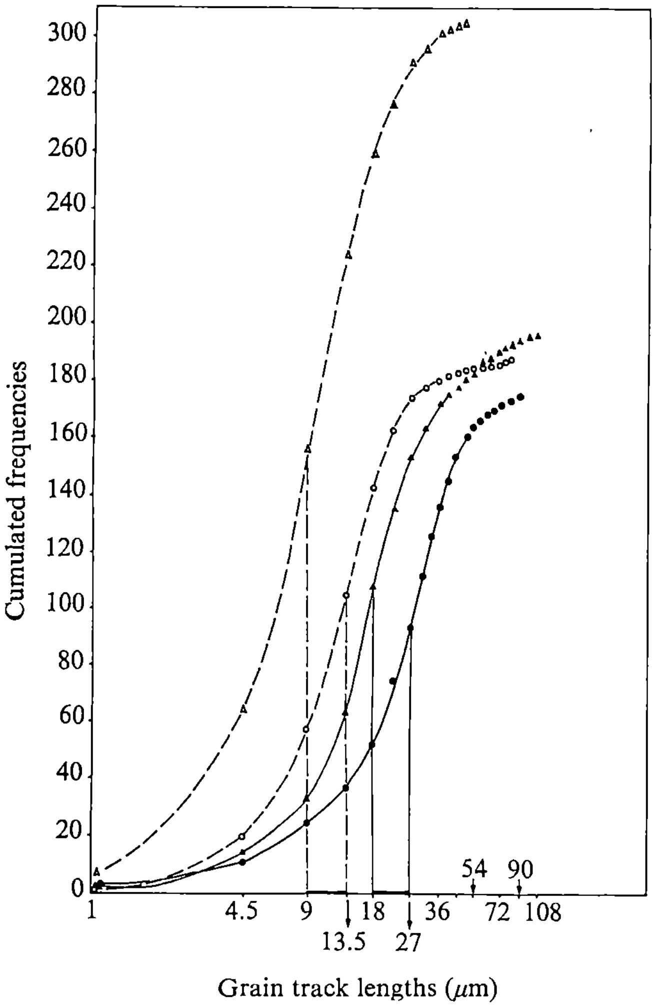
Our data support the conclusion that oestradiol accelerates fork growing rate. The lengthening of labelled segments from experimental uteri does not seem attributable to an increased number of fusions between neighbouring units as, first, in the 30-min pulse histogram, at least, there is no significant increase compared with controls of long fused sections, and second, there is apparently no shortening of intervals which could account for a higher rate of fusion. On the contrary, when pulse labelling of oestrogen-treated material lasted 60 min, the longer size of labelled sections induced artificial lengthening of centre–centre distances as a result of more numerous fusions which are represented by the greater right-hand tail of the corresponding histogram of track lengths. There is, however, a possibility that in addition to increasing replication speed, oestradiol would induce a higher density of operating replicative units which could not be evidenced in our study because of the relative scarcity of centre–centre measurements.

Several authors[1–6] have proposed a reduction of S phase duration in uterine epithelial cells from oestrogen-treated mice ranging from 30 to 60%. In our study the 50% increase of fork growing speed accounts for a 33.3% shortening of S phase. Only a tentative estimate of fork growth rate can be derived from our data. The modal values which were found may be assumed to lie somewhere near unidirectional growth rate since many labelled sections correspond to half replicative units. Moreover, among replicons initiated during the pulse interval, only those in which DNA synthesis started during the first half of the labelling period will show continuous grain tracks longer than monodirectional segments. True fork growth rate should therefore be evaluated at about 0.3 μm and 0.45 μm per min in controls and oestradiol-treated cells respectively. Such values would fall within the range which has been observed in other mammalian cells of which DNA growth rate has been estimated to be around 0.5 μm min^{-1} (ref. 12).

Fig. 2 Cumulated frequency curves and modal values of labelled DNA lengths (log scale) in uterine epithelial cells from control and oestradiol-treated mice. Oestradiol produces a 50% increase in chain growth with both durations of ^{3}H-TdR pulse performed on uteri incubated in vitro. Controls: △, 30-min pulse; ▲, 60-min pulse. Oestradiol: ○, 30-min pulse; ●, 60-min pulse.



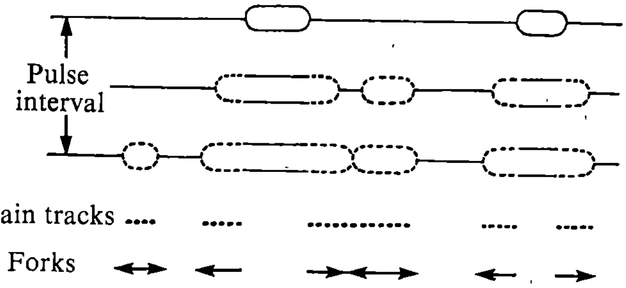


Fig. 3 Schematic example showing how different types of DNA labelled segments can be obtained after single pulse labelling with ^{3}H-TdR (labelled sections in dotted lines). Two replicative units were already operating before giving the pulse whereas two others were initiated at the beginning and at the end of the pulse interval (modified after Blumenthal *et al.*[13]).

Troponin C in brain

The tropomyosin–troponin complex renders actomyosin from vertebrate skeletal muscle calcium sensitive. Troponin itself consists of three subunits: troponin I (TNI), troponin C (TNC) and troponin T (TNT)[1]. Pure TNI (24,000-dalton subunit) inhibits the actin–myosin interaction irrespective of calcium concentration. TNC (18,000-dalton subunit) binds calcium and releases the TNI imposed inhibition. TNT (37,000-dalton subunit) attaches the subunit complex to tropomyosin. Actin, myosin and tropomyosin have been isolated and characterised from a number of non-muscle cells[2,3]. We now describe the isolation and characterisation of a protein from chick embryo brain which is very similar to muscle TNC.

The isolation of this molecule from brain followed our observation that an 8 M urea extract of chick embryo brain contains a protein which migrates rapidly towards the anode in a 6 M alkaline urea acrylamide gel when 5 mM EGTA, a calcium chelator is present (Fig. 1*b*). The protein band has the same mobility as chicken skeletal muscle TNC (Fig. 1*c*). When 5 mM Ca^{2+} is added to the extract, the fast moving band disappears (Fig. 1*a*). This behaviour is similar to that of skeletal muscle TNC, which forms a complex with TNI in 6–8 M urea when calcium is present. EGTA blocks the complex from forming, allowing TNC to migrate rapidly in an alkaline urea gel, whereas the complex migrates much more slowly[4].

We isolated the most rapidly migrating band from a preparative alkaline urea slab gel of a chick brain urea EGTA extract, and analysed the protein by acrylamide gel electrophoresis. The isolated protein was composed of two major polypeptides with molecular weights of 21,000 and 17,000 (Fig. 2*a*). A sample of chicken skeletal muscle TNC (18,000 dalton) is shown in Fig. 2*b*.

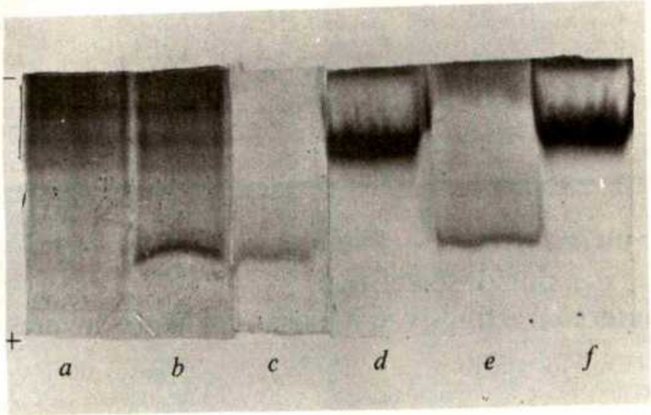

Fig. 1 Alkaline urea–acrylamide slab gels of proteins subjected to electrophoresis as described by Perry *et al.*[4] and stained with naphthalene black. One 14-d-old chick embryo brain from which all visible blood vessels were removed was placed in two volumes of 9 M urea. The brain was then homogenised by 15 strokes in a Dounce homogeniser with a tight pestle. The solution was then centrifuged for 30 min at 100,000*g* and the soluble extract divided into two parts. *a*, Electrophoresis of 0.3 ml of chick brain urea soluble extract in 5 mM $CaCl_2$; *b*, electrophoresis of 0.3 ml of extract in 5 mM EGTA; *c*, 5 µg chicken skeletal muscle TNC purified as described by Greaser and Gergely[1]; *d*, 5 µg of presumptive chick brain TNC and 15 µg of rabbit skeletal muscle TNI, purified as described by Greaser and Gergely[1], dissolved in 8 M urea, 5 mM $CaCl_2$ and electrophoresed; *e*, as in *d* except that 5 mM EGTA was substituted for $CaCl_2$; *f*, as in *d* except that 5 µg of chick skeletal TNC was used instead of the brain protein.

To obtain a pure protein, we used another property of TNC. In the absence of TNI, TNC migrates significantly more rapidly in a alkaline urea gel in the presence of Ca^{2+} than in EGTA[4]. We therefore combined the protein obtained from four EGTA preparative gels, added Ca^{2+} and ran another preparative gel. Again we eluted the most rapidly migrating band and analysed this protein by sodium dodecyl sulphate (SDS)-acrylamide gel electrophoresis. One protein band with an apparent molecular weight of 17,000 was obtained (Fig. 2*c*).

To determine whether the brain protein functions like muscle TNC, we substituted it for rabbit skeletal TNC in an actomyosin ATPase assay containing tropomyosin, TNI and TNT. The results shown in Table 1 indicate that the brain protein can restore calcium sensitivity to the muscle actomyosin ATPase, presumably by interacting with TNI, thereby relieving the inhibition induced by the tropomyosin–TNI–TNT complex, when calcium is present. More brain protein than muscle TNC is required, however, to relieve the inhibitory effect, and the resulting calcium sensitivity is lower than when the muscle TNC is used. It is possible that the affinity of the brain protein for muscle TNI is lower than that of the skeletal muscle TNC, or alternatively the brain protein may be partly denatured after the rather harsh purification procedure.

Following these assays the superprecipitates formed in the presence of Ca^{2+} were collected by centrifugation at 5,000*g* for 5 min. One such superprecipitate was analysed by SDS gel electrophoresis. Rabbit skeletal myofibrils containing the same amount of protein were also analysed (Fig. 2*d* and *e*). A protein band is present in the superprecipitate which comigrates with the brain presumptive TNC. This band is not present in myofibrils. This result suggests that the brain protein can bind to muscle actomyosin.

The brain protein was combined with excess rabbit skeletal TNI in 8 M urea and divided into two equal parts. Ca^{2+} (5mM) was added to one part, EGTA (5 mM) to the other and they were analysed by alkaline urea gel electrophoresis. When EGTA is present, a rapidly migrating protein, with the mobility of TNC is seen (Fig. 1*e*). When Ca^{2+} is present this band disappears and one sees a band which has the same mobility as a complex of rabbit skeletal TNI–TNC, and presumably represents a muscle TNI–brain TNC complex (Fig. 1*d* and *f*).

The amino acid compositions of chick embryo brain TNC and two chick muscle TNCs are shown in Table 2. TNC from skeletal and cardiac muscle has a characteristically high acidic/basic amino acid ratio and a relatively high content of phenylamine as does the brain protein.

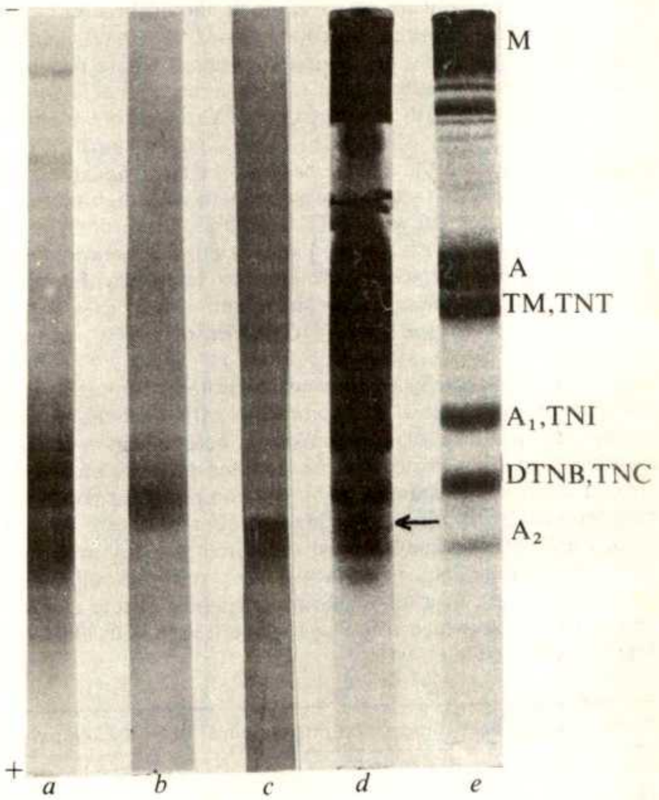

Fig. 2 10% SDS-acrylamide gels of proteins dissolved in SDS and subjected to electrophoresis as described by Weber and Osborn[8] and stained with Coomasie brilliant blue. *a*, 25 µg of protein isolated from preparative urea slab gel electrophoresis of 6 M urea soluble chick brain extract prepared as in Fig. 1 with 5 mM EGTA present; *b*, 5 µg of chick skeletal muscle TNC; *c*, The same protein as in *a* was dissolved in 6 M urea–5 mM $CaCl_2$ and subjected to preparative gel electrophoresis as in *a*. 10 µg of protein eluted from most rapidly migrating band is present; *d*, Ca^{2+}-induced superprecipitate elicited by chick brain TNC. Gel was intentionally overloaded to ensure that the rapidly moving bands were visible; *e*, 200 µg of rabbit skeletal muscle myofibrils. M, Myosin heavy chains; A, actin; TM, tropomyosin; TNT, troponin T; Al, highest molecular weight myosin light chain; TNI, troponin I; TNC, troponin C; DTNB, second heaviest myosin light chain; A2, lightest myosin light chain. This system does not resolve several components into separate bands.

Table 1 Effect of chick brain troponin C on the calcium sensitivity of rabbit muscle actomyosin ATPase in the presence of tropomyosin and troponin I and T*

Troponin subunits added	Mg-ATPase (μmol Pi/min/mg myosin) EGTA	Ca^{2+}	Calcium sensitivity $\left[1-\frac{\text{ATPase EGTA}}{\text{ATPase Ca}^{2+}}\right]\times 100$
a None	0.50	0.50	0
b Rabbit TNI-TNT	0.04	0.04	0
c Rabbit TNI-TNT + rabbit muscle TNC†	0.14	0.57	75
d Rabbit TNI-TNT +chick brain TNC†	0.06	0.11	46
e Rabbit TNI–TNT +chick brain TNC†	0.33	0.55	40

*Assays performed as described previously[9].

†In *c*, 0.08 mg rabbit skeletal muscle TNC added. In *d*, 0.09 mg chick embryo brain TNC added. In *e*, 0.20 mg chick embryo brain TNC added.

These results indicate that the brain contains a protein which is chemically and functionally similar to TNC. The molecular weight of the brain protein is slightly less than that of the muscle protein suggesting either that the two proteins are specified by different genes or alternately that the proteins are products of the same gene and the brain TNC is cleaved after synthesis, or during preparation. It should be noted that brain and other non-muscle tropomyosins also have smaller molecular weights than the muscle proteins, and are products of different gene classes[3].

Proteins similar to the brain troponin C are also present in growing chick sympathetic neurones, and in purified rat synaptic membranes prepared as described previously[5,6]. In both cases a urea extract contains a protein with high mobility in an alkaline urea gel with EGTA present. The protein band disappears when Ca^{2+} is added. Partially purified neuronal and synaptic membrane TNC-like proteins also interact with muscle TNI to form complexes stable in alkaline urea gels. These findings indicate that the brain TNC is at least partially neuronal in origin.

Puszkin and Kochwa[7] isolated a protein complex from synaptic membranes which combined with skeletal muscle myosin to produce a Ca^{2+}-sensitive actomyosin ATPase. Besides containing proteins corresponding to actin and brain tropomyosin in molecular weight, the complex also contained polypeptides with chain weights of approximately 38,000, 27,000 and 20,000. They suggest that these proteins represent TNT, TNI and TNC respectively. Our results confirm the presence in brain of a TNC-like protein and indicate the presence of a protein which is similar to TNI at least in its ability to interact with TNC.

Subunit structure of human hexosaminidase verified: interconvertibility of hexosaminidase isozymes

Two major and several minor isozymes of hexosaminidase (Hex) exist in human tissues. In Tay-Sachs disease Hex A is missing but the activity of Hex B is increased. In Sandhoff's disease, both Hex A and Hex B are lacking; the residual activity represents increased amounts of a normal minor isozyme, Hex S. A fourth isozyme, Hex C, has an electrophoretic mobility very similar to that of Hex S, but seems to be unrelated genetically and structurally to A, B and S. The model which seems best to explain the relationship between Hex A, B and S is one in which they are polymers comprised of two different polypeptides which we have designated the α and β chains[1]. We have proposed that Hex B is a β-chain homopolymer, Hex A an α and β-chain heteropolymer and Hex S an α-chain homopolymer[2]. We now report that all interconversions between Hex A, B and S that are predicted by this subunit model can be performed.

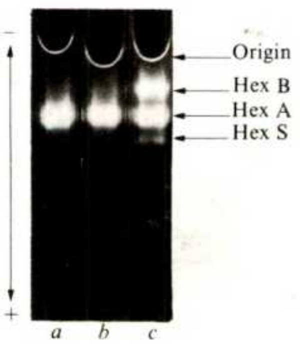

Fig. 1 Acrylamide disc electrophoresis of Hex. A: *a*, untreated; *b*, in buffered 3 M NaCl without freezing; and *c*, after freezing and thawing three times in buffered 3 M NaCl as described in the text. A 7.5% resolving gel in 0.375 M Tris-HCl, *p*H 8.9, polymerised with ammonium persulphate and TEMED, and a 2.5% concentrating gel in Tris (0.06 M)–H_3PO_4 (0.03 M), *p*H 7.2, polymerised with riboflavin were used. The upper buffer reservoir was Tris (0.052 M)–glycine (0.052 M), *p*H 8.9; and the lower reservoir was 0.1 M Tris–HCl, *p*H 8.1. Gels were run at 2 mA per tube for 2 h, and stained with 0.5 mM 4-methylumbelliferyl-N acetyl-β-D-glucosaminide in 0.25 M citrate–*p*H 4.4.

These studies were carried out with homogeneous preparations of human Hex A and Hex B, prepared by methods similar to those described previously[3], but with preliminary purification of the crude placental homogenate on concanavalin A Sepharose[4]. Reactivity with antisera was determined by precipitating enzyme with antibody in a mixture containing 0.04 M potassium phosphate *p*H 7.0, 0.012% bovine serum albumin (hexosaminidase-free), 20 μl of antisera[5] or control serum and 1–5 mU of enzyme. After incubating overnight at 4 °C, the mixture was centrifuged at 40,000*g* for 60 min and supernatant Hex activities were determined. Assays were carried out as before[3].

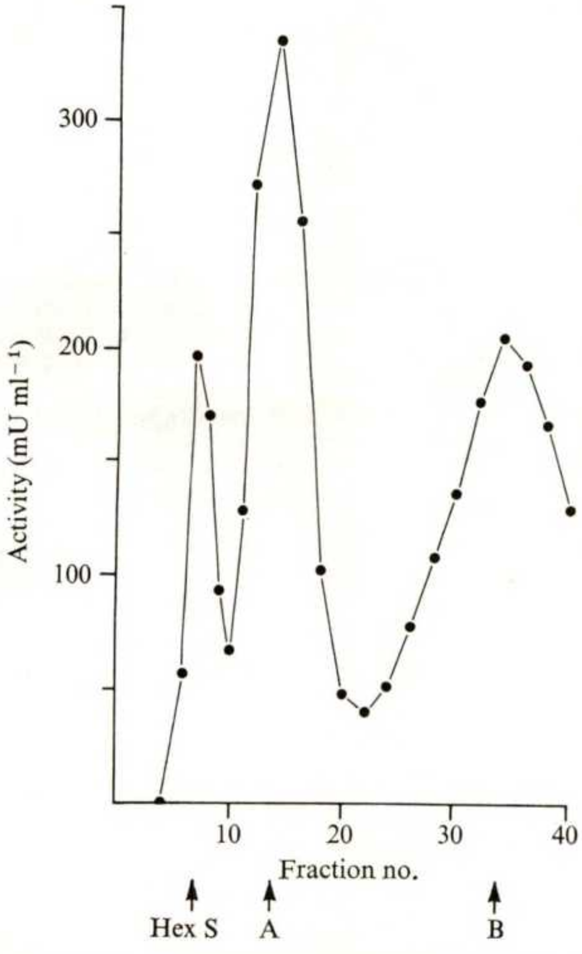

Fig. 2 Elution pattern from preparative polyacrylamide gel electrophoresis of Hex A which had been frozen and thawed in a high ionic strength salt solution. The system described for Fig. 1 was used with a Buchler Polyprep 200 apparatus with the lower buffer reservoir containing a fourfold concentrated buffer. Elution was performed with a 1:4 dilution of this buffer.

Homogeneous Hex A at a concentration greater than 4 U ml^{-1} could be converted directly into Hex B and an enzyme indistinguishable from Hex S by freezing and thawing in 3 M sodium chloride in 0.02 M potassium phosphate buffer, *p*H 7.0. After three or four cycles of freezing in a dry ice–acetone bath and thawing, the enzyme was submitted to acrylamide disc electrophoresis. As Fig. 1 shows, this treatment resulted in the appearance of bands of activity in the positions of Hex B and Hex S, which seemed to reach a maximum after four cycles of freezing and thawing. The formation of Hex B and Hex S could also be demonstrated on Cellogel electrophoresis. The isozymes found in a frozen and thawed preparation were separated on preparatory acrylamide disc electrophoresis (Fig. 2). The putative Hex S isozyme isolated by this procedure was reactive with anti-Hex A (83% enzyme removed) but showed little or no reactivity with anti-Hex B (14% enzyme removed), just as we had found with authentic Hex S obtained from tissues of a patient with Sandhoff's disease[2].

Since an equilibrium mixture between Hex A, B and S seemed to be formed on repeated freezing and thawing, it seemed possible that Hex A could be formed by freezing and thawing a mixture of Hex S and Hex B. As Fig. 3 shows, this was achieved using both the Hex S prepared from homogeneous Hex A (see above) and Hex S partially purified from the liver of a patient who had died of Sandhoff's disease. The Hex A formed by hybridisation of both Hex S preparations with Hex B was indistinguishable from placental Hex A by Cellogel electrophoresis and by DE 52 chromatography. No Hex A was found in a mixture of Hex B and S that was not subjected to freeze–thaw treatment, nor was any Hex A formed when Hex B or S were frozen and thawed separately.

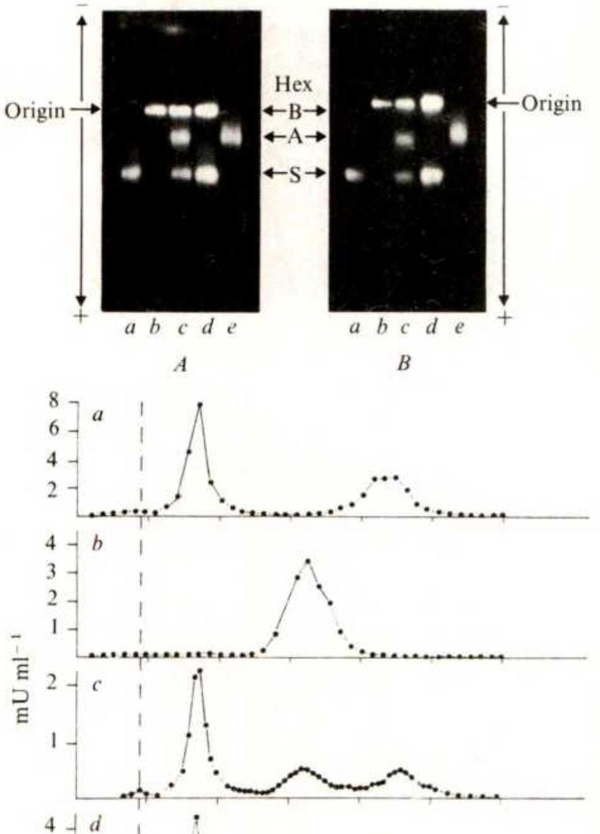

Fig. 3 *A*, Cellogel electrophoresis of: *a*, placental Hex S; *b*, placental hex B; and *c*, a mixture of placental Hex S and Hex B, all of which have been frozen and thawed three times in buffered 3 M NaCl. Channels *d* and *e*, are unfrozen controls of mixed placental Hex S and placental Hex B (*d*) and placental Hex A (*e*). The placental Hex S preparation was prepared from placental Hex A (as shown in Fig. 2). Electrophoresis was carried out for 2 h in a 20 mM potassium phosphate buffer, *p*H 7.0, at 92 V across the gel and 0.6 to 0.8 mA per cm. *B*, the same as (*A*) except that authentic Sandhoff's liver Hex S was used in place of Hex S prepared from placental Hex. A. *C*, Column chromatography elution on DE 52 (ref. 18) of: *a*, mixture of placental Hex S and placental Hex B which was not frozen; *b*, placental Hex A; *c*, placental Hex S and placental Hex B frozen and thawed three times in buffered 3 M NaCl; and *d*, Sandhoff's liver Hex S and placental Hex B frozen and thawed three times in buffered 3 M NaCl.

The close relationship between Hex A and Hex B has been evident for several years: both enzymes are missing in Sandhoff's disease and the two isozymes are strongly immunologically cross reactive. Models proposed to account for this relationship include the suggestions that Hex A is merely the neuraminic acid derivative of Hex B (refs 6 and 7) that Hex A and Hex B are conformers[8], that Hex A and Hex B are unrelated[9], and that Hex A and Hex B have a common subunit[10]. The results of attempts to distinguish between some of these alternatives by studying interspecific somatic cell hybrids have been confusing. Some studies indicated that the presence of Hex B was dependent on the presence of Hex A[11], some indicated that Hex A formation was dependent on the formation of Hex B[12], and others that Hex A and B are unrelated[9,13]. We believe that problems in interpretation of results of interspecific cell hybridisation arise because of difficulties in correctly identifying the enzymes in hybrid clones. Such difficulties are magnified in the case of glycoproteins, because the sugars attached to the protein may vary even from tissue within the same species[14].

Fig. 4 Summary of properties and subunit structures of hexosaminidase isozymes

According to the model we have proposed[1], Hex A has a polypeptide structure of $(\alpha\beta)_n$, Hex B, $(\beta_2)_n$, and Hex S, $(\alpha_2)n$. Our model was derived from, and supported by, the following considerations: (1) the amino acid composition of homogeneous human Hex A and Hex B are different[15]; (2) Hex A contains an antigenic determinant not present in Hex B[1], but all the antigenic determinants present in Hex B are found in Hex A[1,16]; (3) Hex S contained only the antigenic determinants of Hex A and not those of Hex B[2,17]; (4) Hex A can be converted to Hex B and an alkylated α chain by treatment with merthiolate or *p*-hydroxymercuribenzoate[18] (not by neuraminidase, as had been claimed); (5) hybridisation of fibroblasts from Sandhoff's disease and Tay-Sachs disease produced complementation with the formation of Hex A[19]. According to our model, Tay-Sachs disease represents a mutation involving the α subunit, preventing formation of Hex A, $(\alpha\beta)_n$, and making available excess β chains, thus accounting for the increased levels of Hex B, $(\beta\beta)_n$. Conversely, Sandhoff's disease represents a mutation involving the β chain, preventing formation of Hex A and Hex B and making available excess α chains for the formation of the α-chain homopolymer, Hex S. The analogy between this model and the thalassaemias is evident: in α thalassaemia homopolymers of β chains form haemoglobin H, while free α chains are detected in β thalassaemia.

Our ability to interconvert Hex A, Hex B and Hex S demonstrates clearly the correctness of the subunit model. The properties and subunit structures of hexosaminidase isozymes are summarised in Fig. 4. Although we suggested previously that Hex S was probably a homopolymer $(\alpha_2)_n$, a heteropolymeric structure, $(\alpha\gamma)_n$ could not be ruled out in our earlier studies[2]. But the fact that Hex S as well as Hex B can be produced from homogeneous Hex A indicates that no subunits in addition to α and β are required to account for the formation of Hex A, B and S, and that Hex S is, indeed, an α-chain homopolymer.

On the other hand, Hex C, an enzyme which has been described in some detail by Dreyfus, Robinson and others[20] seems to be independent of the Hex A, B and S system. We have been able to show that the residual brain enzyme of our patient with Sandhoff's disease[2] was Hex C, and that it could easily be distinguished from Hex S on side-to-side comparison. We have confirmed the observation that this enzyme, from normal or Sandhoff's disease brain, is not affected by antisera produced against Hex A and Hex B, nor is it precipitated by an antiserum produced against Hex S. It seems likely that Hex C is a genetically independent protein. The minor isozymes, Hex I and Hex S′[2] are probably merely manifestations of the microheterogeneity of the carbohydrate portion of Hex B and Hex S, respectively.

Although the nature of the C, S′ and I isozymes require further study, the interconvertibility of Hex A, B and S verifies their proposed subunit structures. These findings are inconsistent with somatic cell hybridisation studies which assign totally distinct loci to Hex A and Hex B[9] or to the suggestion that the differences between Hex A and Hex B are merely conformational[8].

Stepwise degradations and deamidation of the eye lens protein α-crystallin in ageing

KNOWLEDGE of the intracellular processes of ageing and breakdown of proteins is still very limited[1,2], but the extremely slow turnover of lens proteins in the eye provides a unique opportunity to analyse such processes. Throughout life fibre cells are formed from epithelial cells at the periphery of the lens, being successively covered by younger cells. Protein synthesis ceases soon after the differentiation into fibre cells is completed[3]. As a result the nucleus of the lens of an adult still contains the proteins formed during foetal life. Here we

Fig. 1 Polypeptide chains of bovine α-crystallin and their postsynthetic modifications. The newly synthesised A_2 and B_2 chains are 173 and 175 residues long respectively, showing 57% sequence homology[7,8]. Deamidation in A_2 of 123-Asn and possibly a second amide gives rise to A_1 (W. W. de J., F. J. van der Ouderaa and H. Bloemendal, unpublished). A^{1-169}, A^{1-168} and A^{1-151} are degradation products lacking the last 4, 5 and 22 residues of the normal A chain, and each occurs in two electrophoretic forms, corresponding to the amidated and deamidated state[9,14]. A^{1-101} lacks 72 residues from the C terminus and occurs in a single electrophoretic form[10]. B_1 and B_0 are most probably successive deamidation products of B_2, although the sites of deamidation have not been determined[10]. Removal of five residues at the C-terminal end of B_2 and B_1 gives rise to B_2^{1-170} and B_1^{1-170} (ref. 10).

demonstrate that differences in polypeptide structure observed between the cortex and nucleus[4–6] of the lens are due to an ageing process. Our data provide the first example of progressive degradation and deamidation of a protein, probably caused by non-enzymatic mechanisms.

The polypeptide chains of the major lens protein α-crystallin, a high molecular weight aggregate, are well characterised[7–10] (Fig. 1). It seems that all α-crystallin chains can be related to A_2 and B_2 by deamidation and degradation processes. The proportion of shortened chains increases from cortex to nucleus[10] (Fig. 2), suggesting an age-dependent degradation process, since no protein synthesis takes place any more in the inner cortex and nucleus. These data do not, however, exclude the possibility that the shortened chains are synthesised *de novo* in embryonic lenses, and are present in older nuclei as remnants of this embryonic stage. We therefore investigated the subunits of α-crystallin from prenatal lenses.

It has been shown previously that foetal bovine lenses contain mainly A_2 and B_2 (refs 11 and 12). In very young embryos two additional subunits have been observed[13] which we found by isoelectric focusing to correspond in position to two of the additional subunits of the older lens (Fig. 3*A*). The two additional embryonic subunits were isolated and analysed by tryptic digestion and peptide mapping, using previously described methods[7,8]. The peptide maps were identical to those of A_2^{1-151} and B_2^{1-170} isolated from calf nucleus. Analysis of embryonic α-crystallin by gel electrophoresis in the presence of sodium dodecyl sulphate (SDS) revealed, moreover, the presence in large amounts of the A_2^{1-169} (or A_2^{1-168}) chain, which does not separate from normal A_2 on isoelectric focusing (Fig. 3*B*). Peptide mapping of a mixture of embryonic A_2 and presumed A_2^{1-169} confirmed it to be genuine A_2^{1-169} (ref. 14).

These findings show, therefore, that the shortened chains A_2^{1-169}, A_2^{1-151} and B_2^{1-170} are already present in embryonic lenses. Are these chains then the products of independent genes or postsynthetic derivatives of A_2 and B_2? The absence of A^{1-101} in embryonic lenses proves that it is an ageing product of normal A chains. For A_2^{1-168} and A_2^{1-169} it has already been demonstrated that they are degradation products of A_2 (ref. 14). Both A_2^{1-151} and B_2^{1-170} are present in higher proportions in adult nuclear α-crystallin than in embryonic α-crystallin, increasing from 7 to 25%, and from 5 to 15%, respectively.

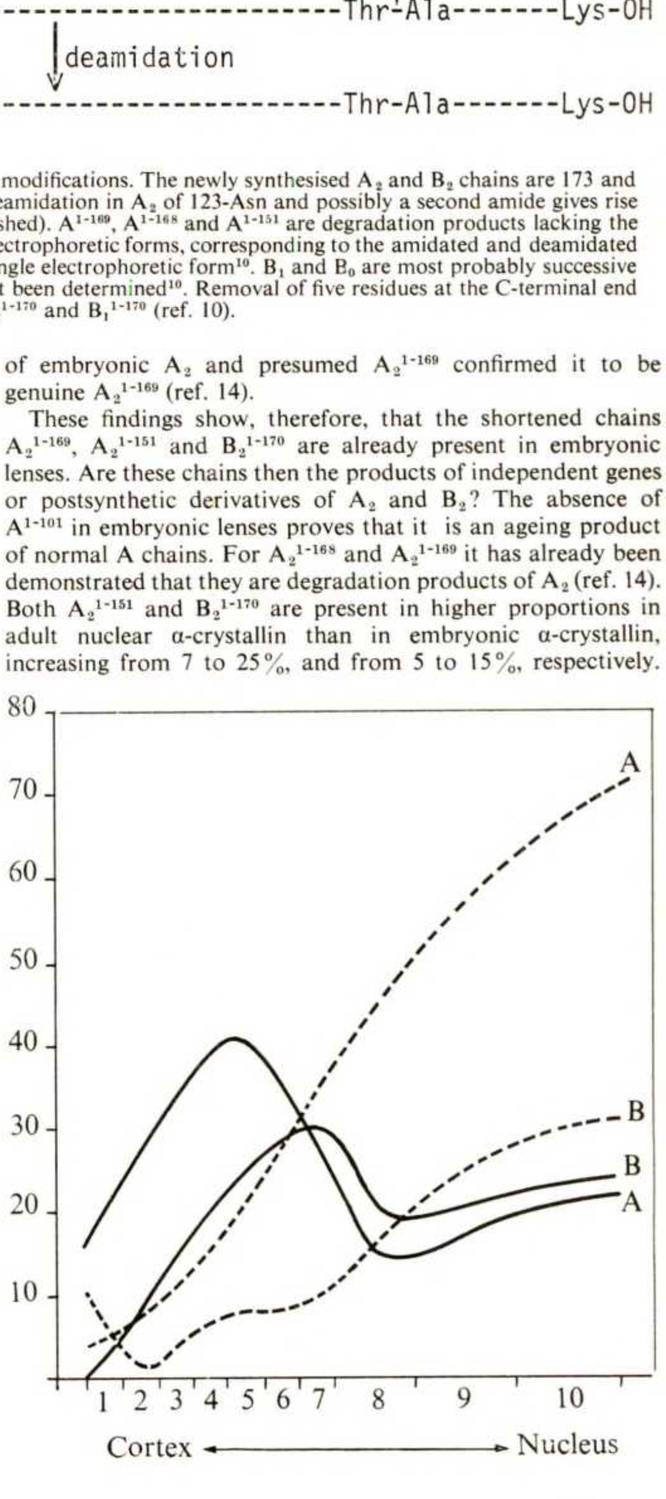

Fig. 2 Ratios of degraded (------) and deamidated (———) A and B chains in α-crystallin from successive concentric layers of calf lens (22 weeks old). α-Crystallin was isolated from ten concentric layers, corresponding to the numbers indicated on the abscissa, and analysed by acrylamide isoelectric focusing. The proportions of the different polypeptide chains were determined by scanning of the stained gels. The values on the ordinate express the percentage of degraded and deamidated A and B chains relative to the total amount of A and B chains, respectively.

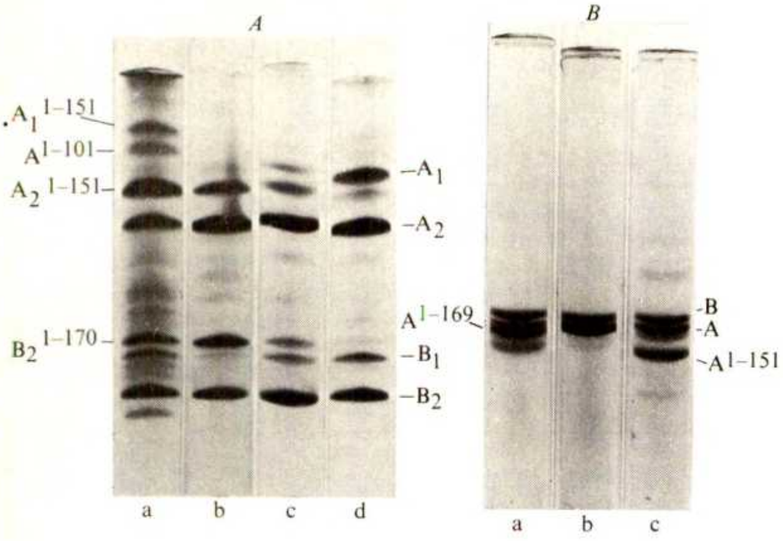

Fig. 3 *A*, Isoelectric focusing gels (*p*H 5–8) in 6 M urea of α-crystallin from: *a*, calf lens nucleus; *b*, 3-month-old foetus; *c*, 6-month-old foetus; *d*, calf lens cortex. *B*, SDS gel electrophoresis of α-crystallin from: *a*, 3-month-old foetus; *b*, calf lens cortex; *c*, calf lens nucleus.

This indicates that the formation of these chains continues in the adult nucleus, which is devoid of biosynthetic activity, and thus demonstrates the postsynthetic origin of these chains. Further proof comes from the fact that A^{1-151} and B^{1-170} can be produced *in vitro* simply by prolonged dialysis of α-crystallin against 0.1 M Tris-HCl buffer, *p*H 7.3 (ref. 15).

Our data thus show that the A_2 and B_2 chains are subjected to two types of postsynthetic modifications: deamidation and C-terminal degradation, as summarised in Fig. 1. The deamidation products A_1 and B_1 only appear in the later stages of foetal life and reach their highest level in the old bovine cortex, where a probable further deamidation product also becomes prevalent: B_0 (ref. 10). Postsynthetic deamidations have been demonstrated in other proteins, and can be obtained *in vitro* in proteins and synthetic peptides[16]. This deamidation process is non-enzymatic and its rate depends on the character of neighbouring residues[16].

The degradation of α-crystallin chains is apparently a postsynthetic process which starts early in embryonic life. The number of degraded chains is, however, clearly largest in the old bovine nucleus[10]. It seems, therefore, justified to consider these degradations as an ageing process. It seems that the chains are preferentially cleft at the sites indicated in Fig. 1. A stepwise breakdown, degrading the A chain successively to 169, 168, 151 and 101 residues, is suggested by the very high level of A_2^{1-169} and the absence of A^{1-101} in the embryonic lens, and the low level of A^{1-168} and high level of A^{1-101} in the old bovine nucleus[15].

Several features make it unlikely that the observed degradations are the result of enzymatic processes. The appearance of A^{1-101} is a very slow process, being most pronounced in the nucleus, which implies that a putative enzyme becomes active only very late after its synthesis. If the enzyme were an endopeptidase it should have a specificity (compare Fig. 1) unlike any known endopeptidase. If it were an exopeptidase it should have carboxypeptidase C-like activity to remove proline residues, and be delayed at the sites indicated in Fig. 1. The fact that degradations can be caused by prolonged dialysis of purified α-crystallin would require that the possible enzyme has the same molecular weight as α-crystallin or that the degradation is an autolytic process. Also the action of lysosomal enzymes cannot be involved, since no lysosomes seem to be present in the nucleus of the lens[17]. In conclusion we propose that the observed degraded chains are the result of non-enzymatic breaks of susceptible bonds.

The knowledge obtained from the age-related phenomena in eye lens proteins may contribute to a better understanding of ageing in general; although it can be questioned whether the processes taking place in the ageing lens are representative of ageing in other types of cells. In addition, the knowledge of normal ageing of lens proteins is of great interest to the study of those forms of cataract which are considered to be the result of precocious ageing[18].

matters arising

Sympathoadrenal medullary activity in young, spontaneously hypertensive rats

INCREASED levels of serum dopamine-β-hydroxylase (DBH) have been reported in spontaneously hypertensive rats (SHRs)[1]. Although DBH is released from sympathetic nerve endings along with noradrenaline, levels of the enzyme in plasma do not seem to reflect accurately the degree of sympathoadrenal activity[2]. Plasma levels of noradrenaline mostly reflect sympathetic neuronal activity whence adrenaline (A) levels are indicative of adrenal medullary discharge. The content of catecholamines and biosynthetic enzymes in the adrenal are presumably indices of the activity of the adrenal medulla in synthesising and releasing catecholamines. The possible role of the sympathoadrenal system in initiating the increase in blood pressure in SHRs was examined by measuring levels of adrenaline and noradrenaline in the plasma and adrenal glands at the age of 4 weeks, the age at which the blood pressure of SHR begins to rise[3]. Normotensive rats of the Wistar Kyoto strain (WKY) from which the SHRs were derived were used as controls. Activities of adrenal tyrosine hydroxylase (TH), DBH, and phenylethanolamine-N-methyl transferase (PNMT), as well as plasma DBH, were also examined.

Table 1 Catecholamine concentrations* and dopamine-β-hydroxylase activity* in the plasma of 4-week-old spontaneously hypertensive and normal rats

	WKY	SHR
Total catecholamines	11.9±0.07	13.2±0.8

§ $0.02 < P < 0.05$.

Male rats, 4 weeks old and weighing 70–90 g, were decapitated, and the first 1.5 ml of blood, which was ejected in a pulsatile stream from the trunk, was collected in heparinised tubes kept on ice. After centrifugation at 6,000*g* for 20 min at 4 °C, an aliquot of the plasma was removed for an assay of the DBH activity[4]. The proteins in 400 µl of the plasma were precipitated by the addition of 10 µl of 40% perchloric acid, and the mixture was kept at −10 °C until it was assayed for total catecholamines (adrenaline+noradrenaline)[5] and noradrenaline[6,7]. The catecholamine content of the adrenals was assayed fluorimetrically[8], and the TH (ref. 9), DBN (ref. 4), and PNMT (ref. 10), activities were assayed radiometrically.

In young SHRs the plasma levels of both the noradrenaline and the DBH were increased over those of the WKY (Table 1) but the total catecholamines (mostly A) were not significantly different. In contrast to the increased TH and DBH activities in the adrenal glands of adult SHR[11], the activities of TH, DBH, and PNMT in the adrenals of 4-week-old SHR were decreased (Table 2). Furthermore, the A content of the adrenals of the SHRs were lower than those of the WKY.

These observations are consistent with the view that, at 4 weeks of age, sympathetic neuronal activity in SHRs is increased, whereas adrenal medullary activity is depressed. Adrenal medullary activity is increased when sympathetic nerves are destroyed by 6-hydroxydopamine[12] and it is likely that depressed adrenal medullary activity may be secondary to the increased sympathetic neuronal activity. The exaggerated sympathetic neuronal activity at that age may be an essential factor in the course of development of hypertension in SHRs.

NAGATSU REPLIES—The findings of Grobecker *et al.*[1] agree with previous results[2] on increased serum DBH of SHRs at 3 weeks of age, and are consistent with the view that sympathetic neuronal activity in young SHRs is increased. As additional evidence, I have found that DBH activity in the mesenteric vessels of SHR at 3 weeks of age is increased, indicating increased sympathetic neuronal activity in blood vessels. Interestingly, DBH activity in the locus coeruleus area of the brain is decreased[3].

In contrast, serum DBH activity and tyrosine hydroxylase (TH) and DBH activities in blood vessels of SHRs at 14 weeks of age do not differ significantly from those of normotensive Wistar–Kyoto rats[4], whereas TH and DBH activities in adrenal glands are increased[4,5]. These results suggest that the increased sympathetic neuronal activity in young SH rats is decreased during the development and establishment of hypertension in adult SHRs and whereas the adrenal medullary activity in adult SHRs is increased.

The results of Grobecker *et al.* on decreased TH, DBH, and phenylethanolamine N-methyltransferase (PNMT) in the adrenal glands of SHRs at 4 weeks of age are of interest and indicate depressed adrenal medullary activity in contrast to increased sympathetic neuronal activity. I have, however, observed a slight but significant increase of DBH activity in the adrenal glands of SHRs at 3 weeks of age[3].

Can supernovae make white dwarfs?

LEVENTHAL and McCall[1] have presented a model for a type I supernova light curve, in which the two sections of exponential decay of the light curve are explained by the accelerated decay of $^{56}\mathrm{Ni} \rightarrow {}^{56}\mathrm{Co} \rightarrow {}^{56}\mathrm{Fe}$, occurring in a fully convective white dwarf which is formed by the supernova implosion–explosion. While they did give reasons why a type I supernova would be expected to synthesise ^{56}Ni, they failed to discuss whether it would produce a white dwarf, a result which is strongly, though not entirely, unsupported by recent calculations.

The problem centres on whether the ^{12}C-detonation model of a supernova, thought to apply to stars in some subrange of 4–$8M_\odot$, can leave a white dwarf, or, indeed, any collapsed remnant. It is already clear (ref. 2 and W. D. Arnett, unpublished) that stars more massive than $\sim 8M_\odot$ all undergo core collapse and produce neutron stars or black holes.

Buchler[3] has assumed various arbitrary central densities, higher than those now thought to be attainable, for half ^{12}C, half ^{16}O, $1.4M_\odot$ degenerate cores and calculated the results for carbon detonations at these densities. At central density $\rho_c = 8.6 \times 10^9$ g cm^{-3}, the star was completely disrupted. In a small range around $\rho_c = 1.6 \times 10^{10}$ g cm^{-3}, his calculation did in fact produce an extended $1M_\odot$ Ni–Fe white dwarf, with the remaining $0.4M_\odot$ being blown off. At $\rho_c = 2 \times 10^{10}$ g cm^{-3} a neutron star remnant was produced.

Couch and Arnett[4] have recently carried out further calculations, using the ^{12}C detonation model and including all effects yet thought of, such as a convective Urca shell, which might postpone carbon ignition and allow the high central densities necessary for collapsed remnant formation to be achieved. Their models disrupted completely, except for the case where the C–O core was initially only 10% C by mass. The carbon burned non-explosively and a remnant could possibly be formed unless the central density reached a critical density (between 1×10^{10} and 2×10^{10} gm cm^{-3}), where the oxygen would ignite. They point out however that if He burning had produced such a low C–O ratio, it might become impossible to understand the nucleosynthesis of C and O, which is, presumably, done in higher mass stars, which are able to preserve and eject these nuclei.

Thus the formation of white dwarfs by supernovae remains highly problematical. If it could be shown to occur, Leventhal and McCall's model of type I supernova light curves would gain much credibility. It could also frustrate attempts (ref. 5 and B. M. Tinsley, unpublished) to deduce the mass below which, stars are able to shed enough mass by the planetary nebula mechanism to become stable white dwarfs, by counting white dwarfs in open clusters with high-mass turn off points on the main sequence.

Carotid body chemoreceptors

THE "New theory for receptor mechanism of carotid body chemoreceptors" proposed by Osborne and Butler[1] requires that the rate of dopamine secretion from the glomus cells be high when blood gas tensions are normal and reduced in hypoxic conditions. The results of new experimental studies[2,3] are incompatible with the 'new theory' because the relationship between secretion of carotid body catecholamines and blood oxygen was found to be opposite to that postulated. In one study[2], the formaldehyde-induced fluorescence of the glomus cells was measured to monitor changes in their catecholamine content. In untreated cats, hypoxia resulted in higher fluorescence intensity of type I cells from innervated carotid bodies than from denervated ones. When cats were treated with a decarboxylase inhibitor, intensity of fluorescence was decreased in innervated carotid bodies compared with denervated organs after hypoxia. Sampson *et al.*[2] concluded that an increase in centrifugal impulse activity in the sinus nerve induced by hypoxia enhanced both release and synthesis of catecholamines in the carotid body. In the second study[3], the content of noradrenaline plus adrenaline in the cat carotid body was measured by the trihydroxy indole method. The content of these amines in the carotid body decreased after hypoxia and increased above the air control level when inspired oxygen concentration was raised to 40%. The decrease in catecholamine content was greatly attenuated when the carotid sinus nerve was cut before hypoxia.

Since the fluorescence technique used measured dopamine as well as noradrenaline and adrenaline, the increase in fluorescence in untreated carotid bodies after hypoxia may be attributed to enhanced synthesis of dopamine, which serves as precursor for noradrenaline and adrenaline. This is the case in the adrenal medulla where neurogenic stimulation activates tyrosine hydroxylase and increases dopamine content while releasing noradrenaline and adrenaline[4]. The results of the two carotid body studies[2,3] are consistent with the idea that stimulation of efferent neural pathways to the carotid body during hypoxia enhances both synthesis and release of catecholamines. The data provide no support for the 'new theory'[1] which requires that hypoxia depress secretion from the glomus cells of the carotid body and postulates that secretion is regulated independently of sinus nerve efferent pathways.

[4] Carlsson, A., and Lindquist, M., *J. Neur. Transmission*, **35**, 181 (1974).

OSBORNE AND BUTLER REPLY—Our conclusion[1] that a catecholamine (probably dopamine) is continuously released from the glomus cells during normoxia, and that the rate of release decreases during hypoxia, was based on the following: (1) glomus cells store large amounts of catecholamines, in particular, dopamine[2]; (2) catecholamines, especially dopamine, suppress or block the chemoreceptor discharge[3,4]; and (3) α-adrenoreceptor blocking agents greatly increase receptor firing rate (up to tenfold)[3,4] during normoxia and the effectiveness of the these blocking agents decreases during hypoxia[3].

It has since been indicated that there is a high turnover rate of catecholamines in the glomus cells, and that it seems likely that these cells release dopamine at a high rate[5]. This catecholamine activity by the glomus cells is envisaged to occur in normoxic conditions. Indeed, the metabolism of catecholamines requires the presence of molecular oxygen[6]. These observations suggest that as the oxygen availability decreases, the metabolism of catecholamines declines.

In the above article[7], the phrase "the increase in fluorescence in untreated carotid bodies after hypoxia" is puzzling in view of the facts that Mills and Slotkin[8] describe a decrease in catecholamine content of the carotid body during hypoxia, and Sampson *et al.*[9] did not in fact make the straightforward comparison between the amounts of catecholamines present in the glomus cells of untreated normoxic and hypoxic carotid bodies. We do not therefore accept that these two papers[8,9] contain unequivocal evidence regarding the effect of hypoxia on the release of catecholamines from the glomus cells of the carotid body.

Furthermore, Mills and Slotkin[8] state that the decrease in catecholamine content of the carotid body during hypoxia is largely mediated by way of the sinus nerve, whereas Sampson *et al.*[9] report that the catecholamine content of the glomus cells of the carotid body was higher in those organs with an intact sinus nerve. In an attempt to reconcile these apparent differences, Mills *et al.*[7] state more precisely that Mills and Slotkin[8] were referring to noradrenaline and adrenaline only, whereas Sampson *et al.*[9] measured total catecholamines. They now conclude that dopamine levels are increased within the glomus cells, whereas noradrenaline and adrenaline are released in response to efferent nerve activity. Whether this effect is mediated through a direct supply to the glomus cells or via the vasculature is not discussed by these authors, but it does raise the important issue regarding which catecholamine(s) is the major agent of chemoreceptive inhibition.

As has been shown[5,10,11], and as pointed out here, dopamine seems to be the favoured candidate.

Spectacle haloes

THE nuclear geophysical enigma of the ^{210}Po haloes[1] is quite fascinating, but the explanation put forward on the basis of a novel form of ^{206}Pb is not easy either to understand or to believe.

If no primordial lead is present, all of the ^{206}Pb, ^{207}Pb and ^{208}Pb found in ordinary U–Th haloes will be derived from polonium α decay. To explain all of the polonium haloes observed by Gentry[1–3] without apparent α-emitting precursors it is not useful to assume new types of stable lead daughter products but rather some unknown, long lived isomers either of ^{218}Po and ^{210}Po or of β-emitting precursors of these. The haloes may be explicable without such an assumption. What is needed is that in a usual halo the polonium isotopes must decay while still in the uranium inclusion from which they are derived, whereas in the enigmatic halo they must together have migrated by at least hundreds of micrometres from their ancestral uranium.

Since the enigmatic halo has an intensity comparable with that of an ordinary halo, it must be attributable to the decay of quantities of polonium corresponding to the total output of a normal, halo-producing, uranium inclusion for at least tens of millions of years. That is a very long period compared with the half lives of isotopes of any elements other than uranium and thorium themselves. Conditions must, therefore, have been such as to allow migration from the original parent sources for very long periods.

The most likely migrant would seem to be lead, since emanation or polonium would give larger haloes than are seen. In that case there would be ^{210}Pb with a half life of 22 yr in one series and ^{211}Pb with a half life of 38 min in the other. Further, the ^{232}Th series, which eventually produces the observed ^{208}Pb, has ^{212}Pb with a half life of 10.6 h as a carrier, though it has no polonium with a half life of longer than 0.16 s. I do not know the temperature required for that migration of lead at a suitable rate, but it is, presumably, fairly high. Geological evidence would be interesting: Gentry himself has described[2] short fission tracks which suggest that some mica matrices may have been at a high temperature for a long time.

I do not claim that this explanation is highly probable—the events to be explained are rare—but Gentry's explanation would seem to require a higher order of improbability. Both ^{218}Po and ^{210}Po would need to have unknown precursors with half lives of a few hundred million years; lead or bismuth precursors would presumably have crystallised out with observable quantities of stable isotopes of the same elements. Finally, Gentry has also found[2,3] a variety of dwarf or other haloes for which he assumes different, otherwise unknown, α-emitters. All of those α-emitters apparently have mutually similar half lives or they would either have decayed too soon or would still be around in observable amounts. One such unknown isomer would be unlikely enough; so many would seem very close to impossible.

GENTRY REPLIES—The crucial question is whether the polonium atoms which formed the polonium haloes were secondarily derived from the decay of uranium and thorium (see, for example, ref. 1) or from unknown isomers[1], or whether they were primordial.

The isomer hypothesis[1] is one way that polonium haloes could have been explained. My present view is that experimental results have ruled out the isomer hypothesis.

As for the postulate that uranium daughter activity provides a source of polonium atoms, I agree that in special cases polonium haloes can form in that manner: hundreds of such secondarily formed ^{210}Po haloes have been found[2] in a uranium-rich coalified wood from the Colorado Plateau. Earlier, when uranium-bearing solutions interacted with the uncoalified wood, numerous sites were formed containing a variety of elements. Uranium haloes subsequently developed around uranium-rich sites and ^{210}Po haloes around Pb–Se inclusions. The absence of ^{214}Po and ^{218}Po haloes means that even though the hydrothermal transport was high enough to permit the accumulation of ^{210}Po and ^{210}Pb to form ^{210}Po haloes, it was too low for many of the nuclides with shorter half lives—^{214}Pb, ^{214}Bi, ^{214}Po and ^{218}Po—to accumulate before decay. Thus, the formation of ^{214}Po and ^{218}Po haloes was inhibited.

Acceptable as that explanation is as far as ^{210}Po haloes in coalified wood are concerned, there are formidable obstacles in using it to account for the variety and distribution of ^{210}Po, ^{212}Po, ^{214}Po haloes in minerals. Except along conduits or cracks where solutions have passed, atomic migration in minerals proceeds by diffusion. Since the r.m.s. distance, x, that an atom of diffusion coefficient, D, will migrate in time, t, is $x = (2\,Dt)^{1/2}$ and the maximum value of D_{Pb} (at 20 °C) in 7 different minerals[3] is 10^{-18} cm^2 s^{-1}, a ^{210}Pb atom (with a half life of 22 yr) would migrate, on average, about 10^{-5} cm before decay. Even at 1,038°C the D_{Pb} value (10^{-11} cm^2 s^{-1}) in microclinepertite[3] yields negligible migration ($x = 0.11$ cm) of a ^{210}Pb atom before decay. Further, this is a somewhat unrealistic case, for even though shortened fission tracks exist in some micas[4], the great majority of minerals containing polonium haloes show no evidence of high temperature episodes. Concerning Po haloes in fluorite I can be very specific. The D_{Ba} ($\simeq D_{\mathrm{Pb}}$) value is less than 10^{-22} cm^2 s^{-1} at 300 °C (ref. 5) and it is certain that the fluorite has not exceeded that temperature during or since halo formation, because halo coloration disappears within minutes in this temperature range[6]. In that case a ^{210}Pb atom would migrate only about 10^{-7} cm before decay.

Thus, if Po or Pb radionuclides were migrating to Po halo radiocentres, most would have decayed in transit and produced a large excess of α-recoil tracks close to the radiocentres, which is contrary to observation[7]. An equally strong objection to the uranium-daughter hypothesis in uranium-poor (p.p.m. or less) minerals is that many Po haloes (such as the 'spectacle' halo) are located in the interior of large pegmatitic crystals as well as in small granitic mica flakes where they are often more than 10 cm and sometimes much less than 100 cm away from a significant uranium source. The fact that ^{214}Po and ^{218}Po haloes often occur profusely in some minerals (10^3–5×10^4 haloes cm^{-3}), whereas their formation was inhibited even in the uranium-rich (16% U) coalified wood where nuclide transport rates were comparatively high, certainly suggests some other origin for polonium haloes in minerals.

But if isomers and uranium-daughter diffusion did not produce polonium haloes in rocks, we are left with the idea that polonium haloes originate with primordial Po atoms just as U and Th haloes originate with primordial ^{238}U and ^{232}Th atoms. Thus, a new type of Pb exists in polonium halo radiocentres, derived specifically from primordial polonium α-decay. Carried to its ultimate conclusion, this means that polonium haloes, of which there are estimated to be more than 10^{15} in the Earth's basement granitic rocks[8], represent evidence of extinct natural radioactivity, and thus imply only a brief period between 'nucleosynthesis' and crystallisation of the host rocks.

If this conclusion is considered highly improbable, then another explanation for the origin of the polonium should exist.

Microorganisms on manganese nodules

WE report here tubular forms found on the outer surface of a piece of coral coated with manganese from the eastern flank of the Mid-Atlantic Ridge (biotrawl at 747 m, V22-D6 Lamont–Doherty Geological Observatory). Scanning electron microscopy (SEM) of a dark zone of the coral revealed well preserved coiled tubular fragments which may be *Saccorhiza* averaging 2–3 μm in diameter (Fig. 1*a*–*d*). These tubular structures were not found on the inner surfaces. They are, however, ubiquitous throughout the dark ferromanganese zones on the outside of the manganese-coated coral. They seem merely to adhere or be cemented to zones rich in ferromanganese which show little distortion (Fig. 1*b*–*c*). We suggest that these organic structures are better preserved on fragments coated with ferromanganese than in the interior of compacted ferromanganese modules such as those studied by Greenslate[1].

reviews

Outweighing bones of contention

By any standards, the life and career of Louis Leakey was extraordinary. Kenyan by birth, Kikuyu by adoption and anthropologist by education he was still more: contemporary historian, palaeontologist, graphologist, museum curator, Criminal Investigation Department investigator, zoologist. But in this age of specialisation he was no less remarkable for his diversification than for his accomplishments, as these two books amply demonstrate.

By The Evidence, the second instalment of Louis Leakey's memoirs, covers the years from 1932 to 1951 and follows the initial volume, *White African,* which dealt with his first thirty years. *By The Evidence* encompasses a period of remarkable and varied productivity but also of serious professional conflict and controversy. These are the years of the initial explorations at Olduvai Gorge, Rusinga Island and other sites, the first Pan-African Congress, the discovery of *Proconsul;* they are also the years of stinging criticism and debate over his claims for the fossil hominids from Kanam and Kanjera. This was also a period of active involvement with police investigations in Kenya and of the development and expansion of the Coryndon Museum in Nairobi into what eventually became the National Museum of Kenya. The book eloquently describes his concern for the vanishing cultures and languages of East Africa; it also documents his efforts and ultimate frustrations in preserving something of the past for the future. His three-volume, 700,000-word monograph on the Kikuyu is still unpublished, although funds from the Leakey Foundation may soon solve this problem.

By the Evidence: Memoirs, 1932–1951. By L. S. B. Leakey. Pp. 276+12 photographs. (Harcourt Brace Jovanovich: New York and London, January 1975.) £2.95.

Leakey's Luck: The Life of Louis Seymour Bazett Leakey, 1903–1972. By Sonia Cole. Pp. 448+50 photographs. (Collins: London, May 1975.) £5.50.

Louis with man-eating crocodile on Rusinga Island, Kenya

Sonia Cole's excellent book, *Leakey's Luck,* is a fine complement to the memoirs. Her close involvement with both the events and personalities she describes makes her book a particular delight. Moreover, her background in prehistory eminently qualifies her as both biographer and critic, and her book constitutes, in fact, a chronicle of studies of early man in East Africa. Although a small amount of fossil human material had been recovered there in the early years of this century, notably "Olduvai Man" by Hans Reck in 1913, it was Leakey's initial work in 1926 which marked the real beginnings of such studies in East Africa.

The controversy which followed so much of Leakey's life began with the report of the human material from Kanam and Kanjera, recovered during the third East African Expedition, in 1931. Leakey contended that the Kanjera skulls and the Kanam mandible represented evidence of an advanced type of human at a very early period in the Pleistocene. This controversy has yet to be finally resolved and his search for a morphologically more modern type of man in the early Pleistocene continued unabated throughout his life. It is ironic that whereas his own candidates for this group, which included *Homo habilis,* have not found wide acceptance in the field, his son Richard's discoveries at east Rudolf have been accepted, almost without equivocation, as very early members of the genus *Homo.*

But Louis Leakey's contributions to the development of Palaeoanthropology as a discipline, far outweigh such "bones of contention", to use Mrs Cole's phrase. In 1947, he organised the First Pan-African Congress on Prehistory, which was held in Nairobi. This Congress represented an important turning point in the evolutionary study of man; not the least of its effects was to remove the focus of fossil man studies from Asia and to re-direct it to Africa where it has remained ever since. At the Congress in 1947 scientists from many different and yet inter-related disciplines met and discussed aspects of their own research involving human evolution in Africa. It was here that Le Gros Clark, in opposition to then widely held opinion, gave convincing arguments why the South African Australopithecines should be included within the human family. It was also at this time that the enormous potential and importance of the East African Miocene deposits became more widely appreciated. As a result of this Congress Leakey received a grant to continue his explorations in deposits of this age and in the following year Mary Leakey found the skull of *Proconsul* on Rusinga Island; to date, this remains the only Miocene hominoid skull known.

Both books are rewarding. *By The Evidence* is a unique and personal anecdotal remembrance, whereas *Leakey's Luck* provides a broad perspective on East African prehistoric studies.

G. E. Kennedy

Spectroscopy from end to end

Molecular Spectroscopy. By Ira N. Levine. Pp. x+491. (Wiley-Interscience: New York and London, June 1975.) £10.50.

Organic Spectroscopy. (A Macmillan Chemistry Text.) By William Kemp. Pp. xvi+248. (Macmillan: London and Basingstoke, June 1975.) £7.95 hard cover; £2.95 paper.

SPECTROSCOPY not only covers a wide frequency range but also has a wide range of interested practitioners from devoted theoreticians to organic chemists. These two books serve opposite ends of this range. Take the area of the ultraviolet spectroscopy of aromatic molecules. An organic chemist, hoping to identify and estimate a small amount of such material in solution before tea-time, would find *Organic Spectroscopy* a valuable reminder, or even introduction, for what is needed. But a PhD student with a research topic to identify the electronic structure and symmetry of an excited electronic state and determine quantitatively its origin, vibrational structure and molecular geometry could usefully study much of *Molecular Spectroscopy* before he starts and all before he faced his examiners.

Both are good books of their kind, although each carries a slight feeling of distilling the best parts of their predecessors rather than adding a new consistent approach. For instance Levine, who is admittedly re-writing parts of, and rearranging, his own earlier book, uses something like a Dirac bra/ket nomenclature for matrix elements but avoids, except for a few equations in chapter 8, the simplicity its full use would bring. He also refers to SI but does not use these units and consequently uses the c.g.s. Gaussian equations rather than rationalised m kg s A versions and associated quantity calculus—as increasingly favoured in schools and essential for consistency with SI. The material seems scientifically sound and reliable and the coverage appropriate, including a new section on photoelectron spectroscopy, although optical rotation and circular dichroism are regrettably absent. I am continually embarrassed by my failure to answer my colleagues who ask "Can you give us a simple picture of what is happening to the molecule and its electrons as optical activity is observed?"

Kemp's book does include this topic briefly, as well as mass spectroscopy. The whole is written in simple language and seems to be appropriate for the bench chemists for whom it is intended, with the slightly more difficult parts identified for digestion at a second reading. The infrared section seems one of the best and I am rather less happy with the one on nuclear magnetic resonance, which attempts to explain sophisticated ideas with a classical picture.

Both are well produced and value for money.

D. H. Whiffen

Intimate knowledge of Wales

The Prehistoric, Roman and Early Mediaeval Field Monuments. By Christopher Houlder. Pp. 207+29 plates. (Faber and Faber: 1975.) £4.50.

FABER'S series of archaeological guides under the editorship of Glyn Daniel grows apace. To the British coverage, already including James Dyer's highly successful *Southern England*, the present volume makes a very welcome addition. It's a surprising fact that this is the first adequate guide to Welsh sites ever to be published.

The author divides the principality into eight regions, determined by the natural structure of the land, and assigns a chapter to each. Within the regional structure all the major sites the listed and briefly described. The text is liberally sprinkled with plans, illustrations of objects and a well chosen series of aerial photographs and includes good references and such tourist information as is necessary. All that, and the accompanying short introductory sections containing information on museums, archaeological organisations, ordnance survey maps, suggested tourist centres and so on, make this an ideal handbook for visitors.

Where the book is a little thin (and this, one suspects, is no fault of the author) is in the actual body of archaeological background information given. Admittedly, there is a seven page outline of the archaeology of Wales which is a masterpiece of intelligent compression, and wherever possible ancillary information is slipped into the main text, but even so it will be difficult for the general user to relate the sites he visits to the development of human societies in the Welsh landscape. The general context would have benefited from a fuller treatment. For the more archaeologically inclined, the bibliography will be helpful and the simple cross referencing scheme will enable the reader quickly to find the principal published account of most sites.

The author is to be congratulated in producing a succinct but invaluable guide to Welsh field archaeology—a distillation of his own intimate knowledge of the landscape and its early inhabitants.

Barry Cunliffe

Erratum. In the Book Reviews Supplement (*Nature*, **258**, November 6, 1975), the reviewer of *The Seas* by Sir Maurice Yonge and Sir Frederick Russell (page 36) was in fact C. E. Lucas. We apologise for any inconvenience or embarrassment this error may have caused.

Nuclear magnetic resonance and biochemistry

Nuclear Magnetic Resonance in Biochemistry: Principles and Applications. By Thomas L. James. Pp. xii+413. (Academic: New York and London, June 1975.) $26.50; £12.70.

IT is now clear that nuclear magnetic resonance (NMR) studies can provide detailed structural, conformational, ionisation and kinetic information about large biological molecules, some of which is inassessible using other techniques. Not surprisingly, many biochemists and biophysicists wish to learn more about the theory and application of the NMR technique. Dr Thomas' book is aimed directly at such readers who will undoubtedly find it useful reading. Starting from first principles, the text describes all the relevant techniques and develops the necessary NMR theory for tackling biological problems. Special emphasis is placed on the theory related to exchange and relaxation effects, which are the most important aspects for biological applications. The theoretical sections are clearly written and, for the most part, the reader should be able to see how the final parameters (such as exchange rates and correlation times) can be calculated from raw data (line widths and relaxation times). In a book of this type, however, it would probably have been useful to work through more examples from the raw data to the final results.

In the section on spin–spin splittings (pages 95–97), a confused definition of the signs of coupling constants is given and it is also incorrectly implied that 1,2-disubstituted ethanes give A_2B_2-type spectra.

An extensive review is given of the applications of NMR to studies of polypeptides, proteins, protein–ligand interactions, membranes and water in biological systems. This section provides an interesting descriptive account of most of the applications to date. Although no attempt is made to evaluate critically the conclusions of the various papers, this part of the book (about 180 pages) constitutes a most useful reference source.

I can recommend the book to anyone interested in learning how to apply NMR to biological problems.

J. Feeney

Dictyostelium discoideum

Dictyostelium discoideum: a Developmental System. By William F. Loomis. Pp. x+214. (Academic: New York and London, May 1975.) $19.50; £9.35.

Dictyostelium discoideum is undoubtedly one of the most intriguing and fascinating organisms that biologists and biochemists have sought to study. It can be cultured as separate amoebal cells showing no apparent cellular interaction and yet at will it can be induced to mass together and develop into a multicellular body that can move and be responsive to light and heat signals in its environment. It is also very good at taking punishment meted out by the curious investigator. It can be squashed, pricked, stained, drugged, decapitated or thoroughly dissociated to separate cells and still resurrect itself and proceed with its planned development. In this book Dr Loomis records and discusses the descriptive and analytical work of many such investigators.

In the early part of the book, the life cycle and various stages of the development are discussed, together with a review of some of the genetic experiments that have been carried out with the organism. After chapters detailing the analysis of cellular enzymes and macromolecular composition, the author then reviews the research concerned with the effects on development of metabolites and such agents as light, heat, cell density, mechanical barriers, dissociation and mutation. The book ends with a discussion of the ubiquitous biological problem of the control of tissue proportions and the various theories that might account for the surprising constancy of ratio of stalk cells to spores in *Dictyostelium*. Such a division into chapters concerned either with developmental stages or selected topics covering several stages must have caused problems for the author over the subdivision of information without causing undue repetition. Generally this difficulty has been skilfully overcome in this book and except for the topic of cell sorting out which is rather awkwardly divided between pages 69–71 and 169–170, the chapter arrangement is rational and helpful to the reader.

The book is written in a style that is lucidly descriptive and unambiguous. The writing lacks flamboyance or sparkle, but whether this is a point for praise or criticism depends on whether one wishes to be succinctly informed or entertained. The illustrations are plentiful and of good quality and include photomicrographs using Nomarski optics and scanning and transmission electron microscopy; they add a great deal to the interest of the book.

The account of the various experiments described in the text is, inevitably, somewhat subjective, although only occasionally is this tendency obtrusive. If any criticism is due, it is possibly to the occasional failure of the author to make it clear whether a particular statement is a considered review of the consensus of opinion or the author's own particular viewpoint.

The author notes in the preface that he has attempted to put into focus most of the major studies on *D. discoideum* and generally I feel that he has been successful. One area of research that might also have been included as a major study is that of the work on radiation effects by Dr R. A. Deering and his colleagues at Pennsylvania State University using normal and γ-ray-resistant strains of the organism. The bibliography which is fairly comprehensive is also lacking in many of the interesting papers from Dr Deering's laboratory.

In general this is an excellent book and I would recommend it to anyone wishing to acquire an overall impression of the past and current areas of research using *Dictyostelium*. Dr Loomis has carefully trodden the narrow path avoiding both superficiality and academic pendantry, and has succeeded in producing a book that is both readable and thought provoking.

Astronomical applications of interferometer

The Intensity Interferometer: Its Application to Astronomy. By R. Hanbury Brown. Pp. xvi+184. (Taylor and Francis: London, November 1974.) £6.

THE original stellar intensity interferometer at Narrabri, New South Wales, finished its program in February 1972, and Professor Harbury Brown has celebrated its achievements and looked forward to the future by writing this account of its construction and use. If only more research programs could be recorded in this way. Reading the book is to acquire twenty years of experience painlessly in a few hours. One can read how physicists proclaimed that the interferometer could not work; that the Australian customs officials were fought for a year and defeated; how the main steel tubes supporting the reflectors sagged; how the reflecting surface was accidentally stripped off; and how parrots pecked through the electric cables. Substitute appropriate personalities and pests and you have a story which could be adapted to describe the progress of many another astronomical project. In many ways the intensity interferometer was vulnerable and exposed to attacks of all sorts, even more so than most telescopes, because of the originality of the design and the rural surroundings. The lessons learned must be appropriate to other ventures.

This is not to say that one is reading a chapter of accidents; far from it, as the difficulties were overcome and most of the book contains a straightforward account of this successful work—for example, one has the full theory of the intensity interferometer and a choice of simpler explanations to suit one's taste. The technical description is given in considerable detail, although without an exact analysis of the system of lenses. The scientific results subsequently described show the power of the new technique. Although the primary program, to determine the angular diameters of stars and their emergent fluxes, was carried out, many other interesting possibilities have arisen from the studies of individual stars and multiple stars. If the reader hasn't already guessed, this leads to a proposal for a new instrument to extend and continue the programs. One is pleased to record that the second interferometer is going ahead and to wish its builders as much success and almost as much excitement.

R. G. Bingham

Cytogenetics

Chromosomes and Cancer. Edited by James German. Pp. xxv+756. (Wiley: London and New York, November 1974.) £17.40.

IT is well established that the great majority of cancer cells have grossly abnormal chromosome complements. Since malignancy is, in essence, a heritable loss of growth control, it is obviously tempting to relate its development to these visible derangements of the genetic material. Because some clearly malignant cells have apparently normal chromosomes, and because the chromosome abnormalities observed seem (with a few notable exceptions) to lack specificity, it has been argued that these microscopic rearrangements are merely a by-product or late result of the malignant process.

The book is the first in a series devoted to cytogenetics, although we are not told what other topics will be covered. It starts rather charmingly with a brief scientific autobiography by Curt Stern, followed by a review (by U. Wolf) of Theodor Boveri's 1914 publication *On the Problem of the Origin of Malignant Tumours* in which the questions of this field were first clearly formulated. The body of the book consists of what are essentially 22 review articles, grouped into four sections: disturbances of the genetic material; cancer as a clone; cytogenetics of certain specific cancers; and special approaches. The chapters stand pretty well independent of one another, with relatively little cross reference. This inevitably leads to some repetition —the classification of visible chromosome damage into gaps, breaks, and so on, is covered by three different authors. There is also some imbalance in the amount of space devoted to different topics—for example, Makino uses 31 pages (excluding references) to review in minute detail the admittedly fascinating but limited subject of canine venereal tumours, which are seemingly transmitted from animal to animal by whole-cell transfer, whereas H. J. Evans covers the entire field of radiation cytogenetics in only five pages more.

As with any multi-author book, styles vary widely. Personally I do not find this a disadvantage. The quality also varies quite considerably, from chapters which are rather dull catalogues of major publications, to some really excellent resumés of complex subjects. I particularly enjoyed David Comings arguing for uninemy—"What is a chromosome break?"—O. J. Miller's section on cell hybridisation, and S. M. Gartler's review of the use of biochemical markers in mosaic individuals (including females heterozygous for X-linked markers) to study the clonal origin of tumours.

The recent and unexpected metamorphosis of the Philadelphia chromosome from a deletion into a translocation caught some authors with their hypotheses showing. In fact, the subject matter of the book by and large antedates the application of chromosome-banding techniques to tumour cytogenetics; and much new information is bound to emerge over the coming years. Dr German writes in his introduction that, for this very reason, it is "a highly suitable time to review previously accumulated knowledge". I thoroughly agree with him. Recent advances must be read in the current literature—a book like this justifies its cost by summarising, in digested and digestable form, a vast and complex literature which will generally be relevant for a good many years to come.

The general standard of contributions is high. I recommend this book to anyone interested in the subject of cancer, either for a quick overview of accumulated cytogenetic knowledge, or as a detailed reference source for those actively engaged in the field.

Martin Bobrow

Defects in solids

Theory of Defects in Solids: Electronic structure of defects in insulators and semiconductors. (Monographs on the Physics and Chemistry of Materials.) By A. M. Stoneham. Pp. xix+955. (Clarendon: Oxford; Oxford: London, May 1975.) £29.25.

THIS is a particularly worthy book, one which has long been needed by theoretician and experimentalist alike. Approximately the first half of the book leads one through a very detailed discussion of all aspects of the necessary theory, stressing the role of the perfect lattice, the electronic structure of the defect, and lattice dynamics. All the major theoretical models are discussed and their shortcomings made clear, in some cases brutally so. I think that the solid-state theorist will enjoy this part of the monograph particularly, although for the beginner it will be a daunting task. Many theorists will also find the second half of the book invaluable as the comparison of experiment and theory is especially well presented. Not only will it be informative, but it may imbue the reader with the motivation, so evident in all Stoneham's work, to attempt calculations of direct applicability to experiments already done and still to be done. This last part of the book will be much used by the experimentalist, not simply "to know what, if anything, they should believe of the present theories" but also because it will give them a clearer vision of the interaction between theory and experiment in solid-state physics.

There are various areas of defect physics which are not treated as they do not fall within the remit of the author to concentrate the electronic properties of defects in insulators and semiconductors. Thus, there is no attempt to treat line and planar defects, nor mechanical properties and defect production mechanisms. If this restricts the readership then the price will do so even more. Such possible restriction is a pity as this is an important book of considerable scholarship.

B. Henderson

Treatise on Solid State Chemistry. Volume 2: Defects in Solids. Edited by N. Bruce Hannay. Pp. xiii+527. (Plenum: New York and London, 1975.) $42.00.

THIS volume is the second in a series of works which aim to present the properties of solids from a chemical viewpoint. Studies of defects, imperfections or impurity ions may be described equally well from a basis of chemistry or physics and this volume has a definite chemical bias but is still suitable for physicists or materials scientists. As the existing literature on defects is predominantly oriented towards physicists it is refreshing to read a book with this change of emphasis. Within the volume seven aspects of defect properties have been selected and each is presented by a different author. Chapter titles range over the following topics: electronic structure and spectra of impurities in the more ionic crystals; colour centres in ionic crystals; dielectric properties; transport properties; semiconductors; magnetic properties; mechanical properties. In a single volume such a range of separate contributions has lead to some differences in the level of presentation but in general the book is suitable for first year postgraduates or people who are unfamiliar with some aspect of solid state chemistry. It is not easy to generalise on the work of seven authors but I felt that the book was clear and informative in those areas with which I am least familiar. In more familiar areas, however, it was apparent that much of the book must have been written several years ago. For an introductory text this is a minor fault but one consequence is that the references tend to be rather old and in an active field such as solid state chemistry this is a pity. Similarly in a few cases defect structures are discussed in terms of outdated models. In spite of these limitations this volume on defects in solids should prove a useful text.●

P. D. Townsend

Principles of Microbe and Cell Cultivation. By S. John Pirt. Pp. x+274. (Blackwell Scientific: Oxford and London; Halstead: New York, 1975.) £10.50.

THIS book has been written for students of microbiology and as a reference book for research workers involved in the problem of microbial cell growth. The treatment of the subject is a clear simple mathematical one which should enable the reader readily to understand the dynamics of the different techniques of cell cultivation.

The book is divided into 25 chapters with an appendix of the symbols and abbreviations used. The initial chapters are devoted to an historical outline and to a consideration of the general parameters of cell growth. Batch and continuous culture methods of cell growth are then discussed. The next four chapters deal with the supply of energy and oxygen to growing cells. The other factors affecting growth, general nutrition, temperature, *p*H and water activity are dealt with in separate chapters. There are a number of chapters of interest to microbiologists involved in the production of materials by microbial processes, for example, product formation, growth lag, and batch cultures with substrate feeds.

The subjects of interest to microbial ecologists are dealt with in chapters on slow growth rates, mixed cultures, and growth on surfaces as microbial films. Finally, growth of colonies on solid media, and mathematical models of biomass autosynthesis are dealt with.

Microbial growth is usually treated as a biochemical phenomenon and many excellent textbooks are available which use this approach. The dynamics of cell growth, however, are usually given only superficial treatment; thus, Professor Pirt's book fills a much needed gap in the microbial literature. But both approaches have their merits and both types of book are needed to obtain a balanced viewpoint.

It would have been useful to widen the discussion a little more to show how the ideas outlined could be applied to specific problems. On several occasions the primary references to the subject are not given.

Overall Professor Pirt's book is a very useful addition to the microbial literature and should be read by all those interested in the dynamics of microbial and cell cultivation.

D. C. Ellwood

The New Mars: Discoveries of Mariner 9. By William K. Hartmann and Odell Raper. Pp. 179. (NASA Office of Space and Science: Washington, DC, 1974.) $8.75.

THIS is in many ways the definitive book to emerge from the Mariner 9 adventure, produced with the cooperation of the Mariner 9 Science Exploration Team. As such it provides a well-written insight into one of the most successful scientific endeavours undertaken by man, and should be of interest to many people outside the circle of specialist astronomers and space scientists. For the price, it is worth having just to look at the lavish illustrations; serious planetary astronomers will not gain much from the text that has not already been published, but they may find the general overview of Mars useful, together with the bibliography provided in an appendix.

John Gribbin

Books brief

Interfacial Electrochemistry: An Experimental Approach. By E. Gileadi, E. Kirowa-Eisner and J. Penciner. Pp. xviii+525. (Addison-Wesley: Reading, Massachusetts and London, June 1975.) Cloth $19.50; paper $13.50.

THIS book is divided into two sections, theoretical and practical. The theoretical section (150 pages) is a brief account of basic interfacial electrochemistry with three chapters covering corrosion, energy conversion and electroplating. The theoretical chapters succeed in the authors' aim of providing the fundamentals of electrode kinetics and double-layer theory; the other three chapters, however, are are inadequate and could well have been omitted.

The rest of the book is an excellent advanced practical text. Fourteen chapters describe current techniques of electrochemistry. The arrangement of the subject matter is good. Starting with the basic electronics (emphasis on op-amps) and reference electrodes, the reader is led through the majority of the important techniques of electrode kinetics and interphase studies applied to well defined systems. There are a few criticisms, ring-disc electrodes are omitted and impedance methods are not given sufficient space; electrometallurgy and electrocrystallisation are not dealt with. But these are of small importance, the main references are there at the end of each chapter and the reader is guided by the Authors to the major works of electrochemistry.

The book is a valuable addition to the literature of electrochemistry, and the price is reasonable by contemporary values.

N. A. Hampson

Normal Values in Clinical Chemistry: a Guide to Statistical Analysis of Laboratory Data. (Clinical and Biochemical Analysis: A Series of Monographs and Textbooks, Vol. 2.) By Horace F. Martin, Benjamin J. Gudzinowicz and Herbert Fanger. Pp. viii+504. (Marcel Dekker: New York, May 1975.) $37.50.

MORE and more pathology laboratory results, especially those of clinical chemistry, are numerical in form. Clinicians are accustomed to interpreting such results with the aid of the normal range, a range of values intended to include those to be expected from a large proportion (conventionally 95%) of healthy individuals. This is clearly a statistical concept, and the statistical problems of estimating the limits of the normal range have received a good deal of attention. In fact these problems are quite straightforward; the real difficulties are logical ones, notably in deciding on what is meant by the "normal" population, and practical ones in obtaining the necessary data.

This book attempts to provide the clinical chemist with the statistical techniques needed to assess normal limits, but the attempt is far from successful. A very large literature, not all of it relevant, is extensively surveyed, but the uncritical approach and lack of logical organisation makes it almost impossible to follow the authors' drift. Explanations of the basic statistical principles vary from obscure to downright misleading. Even the practical problems are quite inadequately handled; it is never quite decided whether or not normal limits can be derived from data relating to hospital patients, and the large effects of the menopause on female biochemistry are not mentioned. Clinical chemists should wait for a better book on the subject, which should be considerably shorter and less expensive.

Miscellaneous

Data on Cytogenetic Registers. The International Advisory Committee on Cytogenetic Registers to the Standing Committee on Standardisation in Human Cytogenetics is compiling, updating and publishing a list of cytogenetic registers, together with summaries of aims, objectives and key elements. The Committee has developed a form for the collection of such data and invites individuals who operate Cytogenetic Registers (either in isolation or as part of a larger register system) to write to Dr. James R. Miller, Department of Medical Genetics, The University of British Columbia, Vancouver, B.C., V6T 1W5, Canada.

The Chinese dimension

A MOST remarkable piece of Chinese science is reported on page 286. It seems that as a result of a major redirection in scientific goals during the Cultural Revolution, the Chinese have been able not only to start issuing credible predictions of earthquakes, but also to save lives by firm action. Such success is bound to raise questions about what lessons we could learn from the Chinese, and whether their very distinctive brand of 'science for the people' could with profit be adopted in other countries.

In many ways the Chinese earthquake programme is a unique one. It has been possible to involve amateurs in the reporting process, even to the extent of asking peasants to pass on news of unusual animal behaviour. It has also been possible to rely on an orderly public response to a warning—something very difficult to envisage in southern California. There is something akin to the feeling of a popular crusade in the whole operation; this is hardly a surprise since in the past hundred years at least 200,000 Chinese have been killed in earthquakes (a hundred times the number of American deaths from that cause). But many of those who return from China express considerable concern that the short term advantages of people-involvement will be rapidly squandered if there is no long term policy of upgrading the role of the scholar and scholarship.

Some scholarly facilities are highly praised—particularly libraries—but there are considerable doubts about the adequacy of postgraduate training; indeed in many cases it is almost non-existent. After a three-and-a-half year undergraduate career, the best that the intelligent student can hope for is to be seconded to some field unit where the problems are intellectually demanding and where, at the least, he may pick up some form of scholarship from an older professor with experience of the former style of graduate education. As a means of mobilising a large technical army and convincing the general public that science is working for them, the present method cannot be faulted. It does, however, pose serious problems when it comes to capitalising on genuinely outstanding talents, and there is some doubt that, amidst the welter of activity on every conceivable front, enough criticism goes into the planning of future work.

The American committee, whose report is described on page 286, writes "the local scientific workers described the experiments in which they are engaged. Discussing their work in this manner is apparently an unusual experience for many of these young scientists, and when we questioned or disagreed with them they seemed unaccustomed to the give-and-take of scientific criticism which is so characteristic of the American scientific establishment . . ." As a result, it seems that the Chinese are ever-enthusiastic to measure anything and to try any longshot, regardless of whether or not there is any sound scientific justification for it. In some cases this could pay off handsomely (it is possible that in monitoring animal behaviour the Chinese could be on to something big), but the pay-off is more likely to be in the West, which is better intellectually and organisationally equipped to take anomalous observations, build, refine and use models. It is to be hoped that delegations travelling out of China have picked up some ideas, too, on the running of science.

One of the intriguing questions that arises from the several tens of exchanges of scholarly delegations in the past two years is whether the obvious interest in China is going to be at the expense of exchanges with the Soviet Union. This is partly a political question, of course, and depends on the future of the triangular relationship between Peking, Moscow and Washington. There is, however, little doubt that if the decision were left to the scientists, many would like to cultivate their Chinese contacts, even though the many close friendships that westerners have with individual Soviet scientists would probably not be paralleled in the more anonymous Chinese situation.

There are perhaps two non-scientific reasons why China is appealing—it has an extraordinarily rich cultural scene, and there is an apparent lack of the endless feeling of being watched which has made so many westerners almost relieved to get out of the Soviet Union. But what excites visitors scientifically is the feeling that Chinese science is involved in a great experiment in mutual help; those who do not have their minds ideologically closed want, in some fashion, to see the outcome of the experiment and even to help participate in it. □

Primitive wheat in Afghanistan, showing variability (FAO photo by E. Bennett)

Future in the past

Modern agriculture threatens to destroy the very means by which it developed. The recent establishment of the International Board for Plant Genetic Resources will help to coordinate international efforts to conserve the rapidly diminishing genetic resource represented by traditional varieties of crops grown for generations. Eleanor Lawrence looks at some of the projects now under way.

MOST of the staple crops grown today were first brought under cultivation thousands of years ago. Cultivated plants have spread out from their original centres of cultivation until they can be found today growing in conditions very different from those in which they originated. In the process they have diversified into innumerable genetically different local varieties, each showing some adaptation to the climate and general environment in which they now flourish.

This reservoir of genetic raw material has in the past been of inestimable value to the plant breeder. Over thousands of years of evolution and selection, genes for resistance to many threatening and economically damaging pests and diseases have arisen. Useful qualities such as cold and drought tolerance have developed in varieties growing at the limits of their range. Plant breeders have constantly returned to the older strains for useful genes which can often be found only in a very few varieties or in their wild relatives. Now, however, this invaluable genetic resource is fast disappearing as a result of replacement of traditional crops by the generally more productive newer varieties.

The small fields of primitive agriculture bear little resemblance to the monocultures of industrialised developed countries. Several varieties of the same crop are often grown together, and the individual plants differ greatly from each other. The wild relatives of the cultivated plant may well be present either as weeds in the field or growing along pathways and field margins.

This variability sometimes results in relatively low yields. Indeed, peasant farmers have often selected for reliability rather than high performance, on the basis that in a bad year a small but dependable yield is better than no yield at all. But it is the genetic mixture itself which makes possible the emergence of desirable new forms by fortuitous crossbreeding. These forms may then be selected simply by their superior ability to cope with local conditions, or directly by the farmer.

Agriculture in the developed countries, where intensive plant breeding has been practised, now depends on a comparatively few varieties of the major crops. When grown with modern aids, such as fertilisers, pesticides and herbicides, these produce yields far greater than those possible with the older highly diverse 'landraces'. The gene pool represented by these highly bred crops, however, is restricted by comparison with that represented by the older varieties. The widespread introduction of new strains into hitherto undisturbed areas of genetic diversity, such as the massive introductions of the Mexican-bred semi-dwarf wheats into India and the Near East, actually poses a grave threat to the continued existence of many primitive strains, which are now found only sporadically and in remoter regions.

Where the introduced crops mean higher yields and a better standard of life for the farmer, the disappearance of the older varieties from the fields is inevitable. But the potentially valuable genes which they contain must be preserved, for they will certainly be needed in future crop breeding programmes. Nobody yet knows the full extent of variation available in traditional crops, and many qualities which could be overlooked now might be the very ones desperately needed in the future.

Although the disappearance of traditional varieties is unlikely to slow down, for many crops a reasonably representative sample of the variation in any population can be conserved easily and economically as seed. Seeds of many species remain viable for years if they are kept dry and cold. The optimum conditions for storing many types of seed are now well-known, and gene banks for most important crops have been established in centres all over the world. The old varieties and their wild relatives have been a fruitful source of genes resistance for pests and disease; moreover, they will always have an important part to play in the never-ending race to breed new resistant varieties before the pests themselves progress.

Unusual cultural characteristics sometimes found in primitive varieties have had a revolutionary effect on plant breeding. The semi-dwarf habit in rice, which formed one of the basic traits of the rices of the Green Revolution, was introduced from a primitive variety found in Taiwan. Scientists at the International Rice Research Institute in the Philippines, where the first dwarf rices were bred, are now attempting to combine high yield with the 'floating' characteristic of rices grown for generations in the deep water rice areas around the great rivers of India and South-east Asia.

International efforts to conserve the rapidly vanishing reservoir of genetic diversity began some 15 years ago when the Food and Agriculture Organisation of the United Nations (FAO) convened a technical meeting on plant introduction and exploration. In 1963 an FAO panel of experts on plant exploration and introduction was established, and in 1968 the Crop

Ecology and Genetic Resources Unit, a special section within the FAO, was set up to act as a clearing house for information on genetic resources and to administer the FAO's programme.

The interest this aroused confirmed that the problem was as grave as had been feared. Moreover, the efforts already underway by individual institutes and the FAO itself were only able to tackle the most urgent problems. A relatively large amount of material has now been collected from the more accessible areas, but remoter regions of the world, which contain much of the remaining genetic diversity in many major crops, remain largely unexplored.

A plan for a worldwide network of genetic resource centres incorporating existing institutes and projects within an international collaborative programme was therefore drawn up at a meeting in 1972 sponsored by three bodies: the FAO, the Consultative Group on International Agricultural Research (CGIAR) and the Technical Advisory Committee to the CGIAR.

The programme is coordinated by a committee created 18 months ago, the International Board for Plant Genetic Resources (IBPGR) This falls under the aegis of CGIAR and has a secretariat in the Crop Ecology and Genetic Resources Unit of the FAO. Its budget in 1975 was some $730,000, and a budget of $1.3 million has been proposed for 1976. A year of fact-finding has resulted in several projects now being undertaken with IBPGR funds.

One of the most important projects from the point of view of coordination and information exchange is the genetic resources communication, information and documentation system (CIDS) project based at the University of Colorado at Boulder. This project is intended to realise the full potential of the collections made, which means they must not only be described botanically, but in such a way that the plant breeder can easily identify material which might be useful in a breeding programme. Botanists and plant breeders who wish to use the materials must know details of the original habitat, morphology and local conditions, which can only be recorded at the time of collection. Information on disease resistance and physiological properties can be added later after proper evaluation.

The CIDS project was originally set up, and is still partly supported, by the Crop Ecology and Genetic Resources Unit of the FAO, with the aim of devising a computer system suitable for recording and retrieving information on crop plant genetic resources. The IBPGR has given its support, allocating $237,000 to the project in 1975. It hopes to provide another $360,000 in 1976.

Through visits to existing collections and intensive collaboration with both collectors and plant breeders, the CIDS team has initiated a transfer of genetic resources records into a storable form through a system (TAXIR/EXIR) which is adaptable to any of the principal types of computer with an adequate memory bank. It is hoped that eventually the inventories of all major collections will be filed on this or some other compatible system, which will allow the user to retrieve the collections from the area or with the particular characteristics he wants.

As for the future, some of the field projects which the IBPGR is to finance out of its own fund for 1976 include the Near-East Regional Programme, a programme for the Mediterranean area centred on the Germplasm Laboratory at Bari in Italy, and the development of a regional programme for south and south-east Asia. The Board is also financing collections of rice by the International Rice Research Institute (IRRI) in Bangladesh, Indonesia and other south-east Asian countries.

Many important tropical forage legumes originate in Latin America—the pastures which support the Australian livestock industry are made up almost entirely of introduced species, many from Latin America—and the Board has also provided funds to begin a three-year programme of collection, conservation and evaluation of tropical forage legumes and grasses there. This work is to be carried out by the Centro Internacional de Agricultura Tropical (CIAT) in Colombia.

Attempts to improve the natural pastures in Latin America have used native legumes such as *Stylosanthes*, *Centrosema*, *Desmodium* and *Macroptilium* which make important contributions to the nitrogen fixing ability of the pasture and its nutritional value. But the improvement has been at best sporadic, and the CIAT programme aims to make a systematic and representative collection of these tropical forage legumes and their accompanying symbiotic bacteria, the *Rhizobia*, as well as some tropical grasses.

Ethiopia is an immensely important region of genetic diversity under stress and is an especially important area of variation in wheat and barley. Although several collecting expeditions have been mounted over the years, by the Germplasm Laboratory at Bari for instance, the region warrants its own regional genetic resources centre, like that serving the Near-East at Izmir in Turkey. The Federal Republic of Germany offered to finance such a centre several years ago, and the first funds are to be spent in 1976.

Natural disasters as well as human activity can threaten genetic resources. An expedition organised by the French Organisation for Scientific Research Overseas (ORSTROM), financed by the United Nations Environment Programme, is now in the Sahel collecting as much as possible of the remaining native varieties of sorghum and millet. The indigenous varieties are particularly resistant to drought, a characteristic not found elsewhere. After a disaster, restocking tends to be carried out with easily available varieties brought in from outside which lack the drought resistant characteristics peculiar to the indigenous varieties. If the native genetic material can be collected and stored, however, it can be used in future breeding programmes and even be reintroduced if such a disaster strikes again.

With so much to be done, the limited funds of the IBPGR are to be used mainly as 'seed' money to start off some urgently needed programmes. Its other task is to identify neglected areas and encourage potential donors to put their money into the most worthwhile projects—a task which will ultimately prove to be equally important.

Eco-business

THOMAS H. JUKES

ONCE upon a mountain there was a man named John Muir. He lived on breadcrusts and tea, and he slept in a blanket beneath the shelter of stunted trees (*Pinus albicaulis*) at timberline. He became famous because he awakened the minds of many people to the need for preserving and protecting the wild meadows, flowers, forests, streams and lakes of the Sierra Nevada and other wildernesses.

But, incredibly, Muir's crusade to save the wilderness gave birth to an organization that became a replica of Big Business. Other groups followed suit. The metamorphosis was an evolutionary process; success attracts money, money employs people, and then the payroll must be met, and, above all, the organization must grow. With fascination, I have watched the change in John Muir's legacy—the Sierra Club. He used to hike with the Club on their annual summer outing to the mountains that started in 1901 and has continued through the years.

For the first fifty years, the outings were on a modest scale. In 1957, the cost of the 28 scheduled trips totalled $1,571, an average of $4 per person per day; and obviously cheaper than staying at home. Then came the boom. In 1972, there were 208 trips, and some cost as much as $1,725 *each* for five weeks, not including jet plane fares. Apparently the Sierra Club has not reached its Limits to Growth.

With growth comes financial responsibility. Those who are engaged in saving the world need money, but they are too busy with important matters to concern themselves with investment. Professional counsellors handle such nagging details. Fortunately, there is a Freedom of Information act that allows such matters to be uncovered. The National Audubon Society, once a birdwatchers' club, has a handsome and diverse portfolio of securities including Strathmore Paper Co., Inland Steel, General Electric, Atlantic Richfield Oil, Walt Disney Productions, Texaco, and Columbia Gas. Moreover, Audubon, the rescuer of birds from slicks and spillage made by the polluting oil companies, has a nice gas and oil business in its Rainey Wildlife Sanctuary in Louisiana which brings in $300,000 annually.

Great huffing and puffing followed these disclosures. The President of Audubon, who used to be Secretary of the Army, said that the Society needed experience in actually producing gas and oil. A police court magistrate, I suppose, should commit a few burglaries to get the feel of the thing. The Sierra Club Foundation is long on Exxon, General Motors, Tenneco, Public Service of Colorado (nuclear reactors), strip-mining firms and pulp-mill companies. The Environmental Defence Fund defended its fiscal environment in 1973 by cashing dividend cheques from Mallinckrodt Chemical, Avon Products, Exxon, and Philip Morris.

Some security analysts say that the relationship of conservationists to petroleum companies is symbiotic, citing the case of the Alaskan Pipeline. The construction of this was delayed because of a campaign, spearheaded by the Sierra Club, after a large stock of steel pipe had been purchased in Japan and delivered to the frozen tundra before the current inflation. The price of crude oil zoomed up during the delay, and now the oil companies are using the low-cost pipe, which will transport oil whose net worth multiplied *in situ* while conservationists fought valiantly on behalf of the caribou . . .

I am told that caribous have developed a habit of sleeping on the wooden drilling platforms in Alaska, apparently to ward off the chill of the permafrost. Oh, well!—John Muir rolled himself in a blanket. May as well keep warm! ☐

international news

A thought for food

by Colin Norman, Washington

To help avert "mass hunger for future decades", there should be an immediate, massive infusion of funds into research on food production and a major overhaul of the agricultural research system in the United States, according to two reports submitted last week to President Ford by the National Academy of Sciences. The reports outline preliminary findings of a two-year study, due to be completed in June 1977, of how research in the United States can help combat the grim prospect of increasing hunger and starvation throughout the world.

Specifically requested by President Ford in response to the World Food Conference, which was convened in Rome a year ago, the reports are surprisingly critical of agricultural research policies in the United States. Although there have been spectacular increases in domestic agricultural production during the past three or four decades—to the point, in fact, where North America is now virtually the world's breadbasket—the reports suggest that research efforts lack central coordination, receive insufficient funds, and pay too little attention to basic studies. The preliminary reports, which are designed to influence the Ford Administration's budget for next year (which is now being prepared), thus offer a prescription for improving the research system, and suggest a number of specific projects requiring an immediate injection of funds.

One of the reports, prepared by a committee headed by Dr Harrison Brown of California Institute of Technology (*World Food and Nutrition Study: interim report*) presents an overall view of how agricultural research in the United States can assist in coping with the world food problem. It draws heavily on the findings and recommendations of the second report, concerned mostly with domestic agricultural research policy (*World Food and Nutrition Study: Enhancement of Food Production in the United States*), which was prepared by a committee headed by Dr Sylvan Wittwer of Michigan State University.

Although it is tempting to suggest that the world food problem could virtually be solved by better distribution of food supplies, the Brown committee points out that, with world population increasing by about 2.5% a year, better food distribution will offer at best a stop-gap solution. A few summary facts speak for themselves.

Developing countries increased their food production by about 2.8% a year during the 1950s and 1960s, an impressive achievement which reflects both increasing yield from individual farms and increasing acreage under cultivation. But their effective demand for food in the 1960s increased even more sharply, by about 3.5% a year, and it will continue to do so for several decades. The result has been a rapid escalation in food imports by the developing countries—a trend which, according to estimates of the Food and Agriculture Organisation, will result in total cereal imports of 100 million tons by 1985.

The Brown committee therefore argues that "the key to adequate feeding of peoples in the developing countries over the coming decades is a sustained trend of very substantial increases in the yield of their farms". The increases, in fact, will have to be even more spectacular than those brought about by the recent introduction of high-yielding varieties of wheat and rice—the so called Green Revolution—and the committee also notes that "there is a parallel requirement for continuing rapid expansion of US yields on our principal export crops".

Such achievements will require "a greatly strengthened research base", the committee argues, and its recommendations essentially boil down to three requirements: increased participation by research institutions and scientists from the United States in international research and development activities; increased attention to several lines of research in the United States which have worldwide implications; and some overdue reforms in the planning and execution of domestic agricultural policy.

● Proceeding from the observation that "it is not feasible in the next decade or two to meet the developing world's massive requirements for research capabilities and research results one country at a time", the committee urges "redoubled US efforts" to help build collaborative international research networks—such as CIMMYT, the International Centre for the Improvement of Maize and Wheat, where Norman Borlaug developed his high-yield wheat varieties. In addition to increased funding for such networks, the committee also urges greater participation by universities and other institutions within the United States in the work of the international research centres.

● As for research projects which merit increased attention, the Brown committee notes that the "prevailing bias" among politicians and research administrators is toward applied research likely to yield quick results. The Wittwer committee is less charitable: "Fundamental research undergirding food production technology has languished for two decades", it asserts. "Because of crop surpluses, political pressures from commodity groups, budgetary reductions, and emphasis on immediately applicable results, a formerly substantial basic research effort . . . virtually disappeared".

The Wittwer committee has consequently drawn up a list of research efforts which have been relatively neglected in the rush for quick results. An expanded research programme on photosynthesis is "urgently needed", the committee suggests. It recommends that federal support of such activities be doubled, from $10 to $20 million a year, and that two or three research institutes be established to spearhead the effort. Similarly, research on nitrogen fixation should receive a large injection of federal funds. "The current funding level of less than $5 million from all sources in this nation for research on biological nitrogen fixation is grossly inadequate", the committee states, and suggests that an immediate escalation to $25 million is needed, followed by a 25% annual increase for the next five years.

Basic genetic research to improve plant yields—including DNA recombination techniques—should also receive a five-fold increase in the present funding level of about $500,000 a year, the committee urges. Other areas singled out for increased attention are the adaptation of chemical fertilizers for use in tropical regions, improved methods of pest control, ways to combat livestock diseases, and a better assessment of land and water resources in the United States.

The Brown committee accepts the need for increased efforts on those projects, notes that "there is little to be gained from identifying research work that needs acceleration unless US Government food research budgets are increased sharply", and recommends that expenditures on agricultural research should be increased by at least 50% over the next two or three years.

● Agricultural research in the United States is funded chiefly by block grants to a conglomeration of many federal, state and private research institutions, and both the Brown and Wittwer committees suggest that it lacks central coordination and direction. It is not the first time that committees of the National Academy of Sciences have criticized the system. Three years ago, in one of the most candid assessments of a federal research effort ever to emerge from the academy, a committee under the chairmanship of Dr Glenn Pound of the University of Wisconsin argued that agricultural research supported by the Department of Agriculture is often pedestrian, badly managed and inefficient.

The Wittwer committee seems to have accepted the thrust of that assessment. It recommends that a top-level National Agricultural Research policy Committee should be established to develop a national research policy. Moreover, the committee states that "many agricultural research administrators are of the opinion that (the Department of Agriculture) has not been an effective proponent of agricultural research, that it does not now provide for adequate consideration of the problems and needs of research in its top-level deliberations, and that it lacks administrative and budgeting arrangements that can effectively guide research in response to national and regional needs". It therefore suggests a number of administrative changes within the Department of Agriculture designed to coordinate the activities of its fifteen research divisions, and to enhance the status of agricultural research.

As for funding mechanisms, the committee urges that diverse sources of support for agricultural research be brought together. It also suggests that more funds should be available for support of individual research projects, assessed by peer-review panels and supported in the same manner that biomedical research is supported by the National Institutes of Health.

Although some of those suggestions were incorporated into the report of the Brown committee, it promised to give more thought in its final report to the manner in which overall food and nutrition policy should be developed.

Finally, it should be noted that the Brown committee clearly acknowledges that, in dealing only with the limited topic of agricultural research, it necessarily neglects some of the prime considerations in the world food problem, such as population, education and economic planning. Moreover, the committee also states that it does not "assume superior US wisdom on how to achieve development purposes, but only a capability and willingness to handle research problems and to collaborate with others in problem solving where our participation is welcomed". □

Pesticide perspective

ANOTHER shot was fired last week in the long-raging battle between two of the main schools of thought on the balance to be struck between solutions to the world food problem and their environmental consequences.

Dr Cleve Goring, the director of research and development in plant science for the American-based conglomerate Dow Chemical, nailed his colours firmly to the mast when he spoke at the British Insecticide and Fungicide Conference, held in Brighton.

The three-fold increase in world food production needed by the end of the century to feed the world, he said, would probably require a five-fold increase in the use of pesticides. But he warned that pesticides would, along with other agricultural aids, only help to buy time, rather than solve the long-term food problem.

Dr Goring further warned that "extremists" in the "environmental movement and medical research establishment", especially in the United States, would cause the "unjustifiable elimination" of many products now in use from which the future demand for pesticides would primarily be met. They had to "develop some perspective on the largely imaginary horror of a 'Silent Spring' and the minute amounts of pesticide chemicals that occur in our food".

In speaking out so strongly, Dr Goring drew attention to the apparently increasing plight of even the largest chemical companies engaged in pesticide production. There is evidence that work on new pesticides is being cut not simply as a result of the effects of the recession on research and development but also because the returns are too low for other reasons.

It is accepted even by some environmentalists that the balance is wrong between the time it now takes to develop a new product and the period that the patent laws last. Moreover, it has now become apparent that the new products least likely to yield an economic return are actually the safest in environmental terms because they are also the most selective in their effects.

Dr Goring referred to these matters when he outlined four problems of special concern in the development and use of pesticides:

- The excessive time required in some countries to bring a product from the discovery stage to the market place.
- The need for a "benchmark system" to evaluate the environmental acceptability of new pesticides.
- The lack of agreement between countries on uniform test procedures and tolerances.
- The lack of a workable policy for products reputed to be carcinogenic.

On the increasingly difficult problem of carcinogenicity, Dr Goring had a sharp word for the US Environmental Protection Agency (EPA). He described its recent list of cancer principles as "perhaps the most serious problem", and pointed out that a published list of suspected carcinogens included "many of the natural materials essential to living systems".

But given Dow Chemical's place in the market—sales of pesticides and consumer products last year accounted for more than 10% of its total sales of almost $5,000 million, making it the eighth largest chemical company in the world—Dr Goring's concern was naturally with what he called "over-regulation" of pesticides, which had advanced "beyond all reason".

He was reflecting the view of those who believe that the chances of further chemical breakthroughs were now being reduced. But this view seems to be about as widespread as the environmentalists' belief that there are enough pesticides in existence already. Between the two, however, is an even more widely argued contention that it is not so much the pesticides themselves which are dangerous as the manner in which they are used. As one expert put it last week, "people need not be against their use, only against dangerous substances carelessly used".

Nuclear deals proliferate

THE path towards nuclear non-proliferation is tortuous and often contradictory. This was revealed again recently when more nuclear deals involving less developed countries were announced at about the same time as further meetings of the Nuclear Supplies Group took place in London.

The group, whose members include most of the world's nuclear countries–the USA, the USSR, the UK, France, West Germany, Canada and Japan—wishes to prevent the use of fissile waste products for the manufacture of nuclear weapons. But some of its members are also solidly encouraging the use of nuclear power outside their own privileged circle.

In recent months deals have been reported between France and South Korea for a plutonium separation plant, and between West Germany and Brazil for complete nuclear systems including fuel reprocessing. Secret dealings between West Germany and South Africa have also been brought to light.

Now the UK has joined at least six other countries, including Australia and South Africa, which are interested in Iran's ambitious nuclear programme, and has announced a dual agreement that offers both training and technical assistance, but no reactors.

And the United States apparently promised Egypt two nuclear power reactors, for use in desert desalination plants, during President Sadat's visit to Washington earlier this month. At the same time, the influential Cairo newspaper *Al Ahram* reported that it was Egypt's intention to build 10 nuclear power stations during the next 20 years.

Large as it is, the Egyptian programme barely holds a proverbial candle to that planned in Iran, where the general aim is to make nuclear power the prime source of energy in the country by the 1990s. This will involve some 20 reactors with a combined capacity of around 23,000 MW—more than double Egypt's proposed 10,000 MW, which is its target for the year 2000.

Fears that Iran may be tempted to establish itself as a full nuclear power have not yet manifested themselves as they have over Egypt's plans, in spite of the stimulus that India's nuclear explosion obviously gave to the Shah. The Middle East situation, where Israel's nuclear potential has increased, looms larger in the diplomatic mind, as Dr Kissinger implied when he quickly confirmed that an acceptable arrangement to safeguard the security of the by-products had been worked out with Egypt.

The issue is clearly important to the Nuclear Suppliers Group. The British Foreign Secretary, Mr James Callaghan, emphasised the matter at the UN in September, pronouncing that "the statesmen of the world have a moral duty to act before it is too late to work out the means of controlling the nuclear threat". The talks in London, in fact, were apparently convened in order to discuss the proposals he had made in the General Assembly.

In the meantime, however, the nuclear countries continue to deal among themselves. The British Nuclear Power Company has signed an "enabling agreement" with the Soviet Union on the exchange of experience, techniques and possibly materials connected with the so-called 'steamer' reactors due to come into operation in the UK in the 1980s but already working there. And the efforts to bring Canada's successful technology to the UK continue.

There is evidence of increasing resistance within the nuclear countries to the elaborate nuclear power programmes at home But so far nothing similar has revealed itself in countries wanting such programmes. Only the Nuclear Suppliers Group is showing signs of concern. But it is only the Nuclear Suppliers Group that is acting. to satisfy those wants. □

Round Britain

TEN countries agreed last week on a multi-million pound international programme of five research projects, all based in the UK, designed to develop new technology in the use of coal and so help to solve the energy problem.

The biggest project, costing £10 million, involves the design, construction and operation of an advanced experimental plant near Barnsley which will apply a new technique to coal. It will be financed by the UK, the USA and West Germany.

The technique, known as fluidised combustion because powerful air jets turn burning coal into a bed of red-hot ash that looks and acts like boiling liquid, is said to offer important advantages over conventional steam-raising plant.

Its compactness means a lower capital cost—a big advantage in an era of economic stringency. In addition, it has a high thermal efficiency even with low quality coal, and it cuts pollution by retaining sulphur in the ash bed. It is these advantages which the project is designed to assess.

The other four projects, which cover research services, will together cost about £1 million a year, to be financed by the 10 countries—Austria, Belgium, West Germany, Italy, the Netherlands, Spain, Sweden, Turkey, the UK and the USA

These aim to estimate the reserves of economically recoverable coal, provide information on coal as an energy resource and assess the costs of new techniques for mining and using coal. A mining technology service will also be established.

The programme is the result of the efforts of the coal technology working group, operating under the aegis of the International Energy Agency. The group is headed by Mr Leslie Grainger, the science member on the UK's National Coal Board, which will be the operating agent for each of the five projects. The hope is that the programme will cut the costs of heat for industry and for generating electricity by making a more efficient use of coal.

● An agreement concluded earlier this month will effectively make the UK's Chemical Society owners in the British Isles of all the abstract data produced by the American Chemical Society's Chemical Abstracts Service (CAS) In exchange, the CAS will receive payment in kind in the shape of the specialised expertise developed by the UK Chemical Information Service (UKCIS), a part of the Chemical Society based at the University of Nottingham.

Chemical abstract services are quite big business nowadays, with a total of 5 million chemical compounds known at present and 5,000 new ones being discovered every week. Chemists report their work in fully 14,000 journals.

Even keeping up with the abstracts is itself a considerable chore for many chemists, and the cynics say that it is sometimes quicker to do a simple experiment (to determine a melting point, for example) than to look up the information in *Chemical Abstracts* (the present five-year index of which runs to 68 volumes!).

Although the CAS spends some $25 million a year putting the abstracting material on to a computer and producing *Chemical Abstracts,* it has paid little attention to the problem of how to manipulate further such a vast data base. In the USA, information centres run by bodies like Battelle and Lockheed reprocess the information for their own particular purposes.

The UKCIS, however, has made a point of developing personalised services by making available to individual chemists a current-awareness service which caters for their individual interests. It also, for example, publishes subject-oriented bulletins, 'Macroprofiles'.

At present the UKCIS markets and distributes *Chemical Abstracts,* and some other publications and services of the CAS, in the British Isles. As its contribution to the CAS it also produces the 5% or so of all CAS abstracts and index entries which originate in papers published in the UK.

The annual budget of the UKCIS is, however, small beer by comparison with its American counterpart. Its non-capital expenditure at present is £1.2 million a year. But, like the CAS, its aim is to break even.

The UKCIS can obviously widen its horizons quite considerably now that it is much more than simply an agent for the CAS. In particular, it is actively considering, together with the Department of the Environment, the setting up of a data bank on environmentally significant chemicals Called DESCNET, it would allow biological data on chemical compounds to be stored with other information about them and "should assist in the freer flow of information concerning potential environmental hazards".

● The Post Office exhibited much of its current work in telecommunications research and development last week when the Queen opened the new £11 millions Post Office Research Centre at Martlesham Heath in Suffolk. But most of it was unexpectedly overshadowed by the news that the Post Office is to place major contracts with the telecommunications industry for the development of a computer-controlled switching system code-named System X.

The new system, which will use the latest microelectronics technology, will lead to a modern telecommunications network in Britain capable of handling the wide range of services expected to be in demand by the 1980s, including visual transmission and high speed data print-outs. The development of System X, which is expected to take from five to seven years and cost up to £100 millions, is reportedly the biggest single item of expenditure of the Post Office's annual research bill.

The joint development programme will involve about a dozen contracts with such firms as Plessey, GEC, STC and Pye TMC, the final details of which have yet to be drafted. Advanced as System X is compared to existing telephone switching systems, it is unlikely to supercede current Post Office research work in this field. Both the new waveguide system, which is capable of handling up to half-a-million transmissions simultaneously, and developments in the field of fibre optics will provide important contributions to it. Indeed, it is because System X is based on a series of sub-systems that it offers the Post Office a good degree of flexibility as the development matures.

● A research team at the Harwell Atomic Energy Research Establishment has developed a miniature, nuclear-powered battery which may, quite literally, provide a boost to sufferers with certain types of heart disease. Designed to fit into a small "pacemaker", the new battery works on the thermocouple principle, and because the power output of its plutonium 238 heat source falls off by only about 1% a year it could have an implanted lifetime of 10 or even 20 years. By contrast, conventional chemical pacemaker batteries rarely operate for more than three years before they need to be replaced surgically. The Department of Health and Social Security has ordered 100 pacemakers from British Nuclear Fuels Limited (BNFL) for chemical trials, and the device, now costing about £2,000, could be worth about £10 millions to BNFL

correspondence

Food for thought

SIR,—Dr Magnus Pyke in his article "All the food that's fit to eat" (October 23) notes that the "Society of Public Analysts, now the Society for Analytical Chemistry", was established in the same year as the Sale of Food and Drugs Act 1875. In fact, the first president and council of the new society were elected in December 1874, and were instrumental in influencing certain amendments to the 1875 Act, which was first introduced to the House in February 1875. The society was known as the Society for Analytical Chemistry from 1954 to December 1974, and from January 1975 has continued its activities as the Analytical Division of the Chemical Society.

Yours faithfully,
F. D. GRIMMER

The Chemical Society,
London W1, UK

Aiding Vietnam

SIR,—In his report "Vietnamese Journey" (November 6) Arthur Galston put forward various suggestions for an American aid programme to help Vietnamese scientists. These included sending scientific literature, equipment and visiting scientists to Vietnam.

On the British scene two of these recommendations have been in operation for several years. The Medical Aid Committee for Vietnam has sent considerable quantities of current medical literature to doctors in Vietnam since 1967, and in 1973 began sending scientific literature to Professor Hieu. Many British scientific institutes have assisted us in this work by making donations, including the Biochemical Society, the Institute of Physics, the Royal Statistical Society and the Nutrition Society. Similarly many libraries, including the Library Association, now contact us when they have material which is surplus to their requirements and which we consider suitable for dispatch. All literature is sent free of charge, courtesy of the Soviet Red Cross.

Regarding scientific equipment and chemicals, the Trade Union Committee for Reconstruction in Vietnam has sent material worth some thousands of pounds to Professor Hieu for use in both the north and south of Vietnam.

On a more institutional level, Professor N. W. Pirie last year visited North Vietnam on behalf of the Royal Society and this year the British Government made a donation of scientific, medical and English literature to three institutes in Hanoi.

Several scientific institutes in the UK have expressed a desire to continue to supply current literature to Vietnam. This could easily be arranged, either through the British Council or the Ministry of Overseas Development, and would not require excessive funds. Our committee put forward these suggestions to both the British Council and the Ministry several months ago and we are waiting for their decision.

Perhaps now that more British scientists are aware of the problems facing their Vietnamese colleagues as a result of Professor Arthur Galston's article, there will be greater developments in the British aid programme to Vietnam.

Yours faithfully,
A. HAY

Medical Aid Committee for Vietnam,
London WC2, UK

Journal guidelines

SIR,—It is good that you saw the purpose of the document on "Authors, Editors and Referees" issued by the Scientific Information Committee of the Royal Society—that is, to initiate well informed discussion on this fundamental element of the communication system of science, and to bring into the open the actual procedures that are used (November 6). Indeed, it is only by showing that these procedures are honest and just, giving a fair weight to the interests of all parties concerned and to the needs of the scientific community at large, that we can justify our resistance to the demand to disclose the names of referees to authors, and similar populist follies.

You are also correct in pointing out that the proposed 'guidelines' are not appropriate for your own journal. We are all happy with the thought that *Nature* is almost unique in the world of science. And I would not apply precisely this code to a review journal such as *Reports on Progress in Physics.* But the question whether editors of conventional primary research journals are well advised to deviate very far from the suggested code is worth open and collective debate and should not be confined to laboratory coffee clubs or to the committee rooms and editorial boards of individual learned societies.

May I suggest that by discussing this document in an editorial, quoting only points with which you disagree, you underestimate the intelligence and good sense of your readers, who might like to decide for themselves whether it had some merit in general. Since the whole 'code' is scarcely longer than this letter, why not publish it in full for wider discussion?

Yours faithfully,
JOHN ZIMAN

University of
Bristol, UK

Here it is:

(i) Every paper submitted to the journal for publication should be refereed.

(ii) Referees are appointed by the Editor, and report to him.

(iii) The name of any Referee may only be disclosed to the Author by permission of or at the request of the Referee, with the Editor's agreement.

(iv) The Referee may not disclose the contents of a paper submitted to him, nor make use of these for his own scientific work before publication, without explicit permission of the Author, to whom the name of the Referee must then be disclosed.

(v) The Referee's report should contain a definite recommendation concerning publication based upon a reasoned judgement of the general form and scientific contribution of the paper as a whole. He may recommend acceptance outright or subject to revision of certain sections along specified lines, or may propose that the paper be substantially rewritten to improve the presentation or to strengthen the scientific argument. The substance of all such critical comments should be communicated to the Author for action, to the eventual satisfaction of the Referee. But failure to accept the Referee's view on all minor points of criticism should not be a bar to publication.

(vi) No paper should be rejected on the adverse report of a single Referee.

(vii) In the case of conflicting opinions, the Editor may appoint further Referees or an Adjudicator who may read all communications between the Author and Referees (whose names need not be disclosed to him).

(viii) A definite procedure should be established for Editorial decision within a stated period.

We disagree with i, vi, and viii (but see our statement of editorial procedures on page 1 of the November 6 issue) and would like to hear what others think.

ED.

news and views

Successional patterns and indices of diversity

from Robert M. May

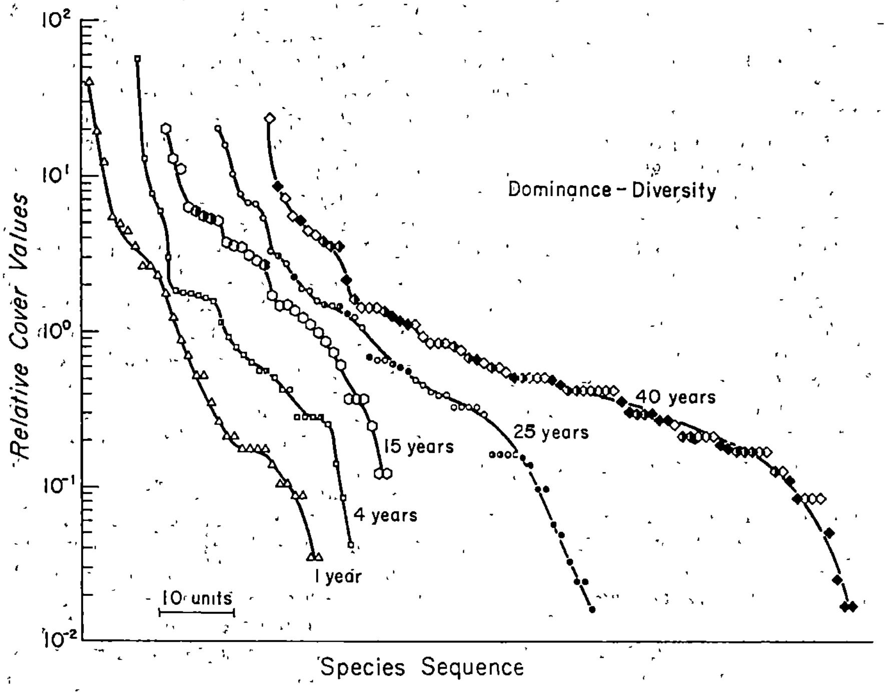
ONE way to quantify Robert Louis Stevenson's belief that "the world is so full of a number of things" is simply to count how many things there are. The result gives the 'species richness', the number of plant or animal species observed to be present in a given community.

But usually one wants to know more than this. If 20 species are present, are they roughly equally abundant, or is one common and the other 19 rare? A full answer to this question involves finding the distribution function which describes the relative abundance of all the species in the community. On the other hand, one may wish to settle for less, and be content with some statistical moment of the distribution, some single number, which characterises the diversity of community. A large (and often muddled) amount of the ecological literature is devoted to the search for such 'diversity indices'. A lucid account of some mathematical aspects of these questions is in the monograph just published by Pielou, *Ecological Diversity* (Wiley; 1975).

Field studies of the relative abundance of species in a variety of plant and animal communities have revealed interesting patterns, many of which can be plausibly explained on theoretical grounds. In the early stages of succession, plant communities will tend to consist of a handful of weedy, pioneer, r-selected species that happened to get there first. The species arriving first will tend to grow rapidly, pre-empting a fraction (*k* say) of the available space or other governing resource before the arrival of the next species, which in turn will tend to pre-empt a similar fraction of the remaining space before the arrival of the third, and so on. The consequent pattern will be, very roughly, a geometric series in relative abundance. As succession proceeds, things become more complicated, and a multitude of ecological dimensions are likely to be relevant to the ultimate composition of the community. That is, in later successional stages the relative abundances of the various species are governed by the interplay of many more-or-less independent factors. It is in the nature of the equations of population dynamics that these several factors should compound multiplicatively, and the statistical Central Limit Theorem applied to such a product of factors implies a lognormal distribution (that is, a bell-shaped gaussian distribution in the logarithms of the species' abundances). Once many species are involved, a lognormal distribution gives a much more even pattern of species relative abundance than does a geometric series distribution: the lognormal is a socialist society compared with the feudal hierarchy of the geometric series.

These notions are in accord with the data obtained from several studies of plant succession at various locations in the temperate zone (see, for example, Whittaker, *Communities and Ecosystems*, ch. 4, second ed, Macmillan, New York; 1975). The patterns show up with particular clarity in the recent study by Bazzaz (*Ecology*, **56**, 485–488; 1975) of old fields in southern Illinois, at successional stages varying from 1 to 40 years. When the logarithm of species relative abundance is plotted against the rank of the species in an abundance hierarchy, early successional stages show the straight line relationship characteristic of a geometric series, while later stages show a progressively more S-shaped curve, with a preponderance of "middle class" species, characteristic of a lognormal distribution. The figure, taken from Bazzaz's paper, makes this plain.

Something akin to a reversal of these successional patterns takes place when mature communities become polluted. This has been shown particularly for streams and lakes subject to "enrichment" by waste heat, sewage, and other materials. The most detailed studies are those of Patrick and coworkers on the changes in patterns of species relative abundance in diatom communities. The equilibrium diatom community essentially always



Patterns of species relative abundance in old fields of five different stages of abandonment in southern Illinois. The patterns are expressed as the percentage that a given species contributes to the total area covered by all species in a community, plotted against the species' rank, ordered from most to least abundant. Symbols are open for herbs, half-open for shrubs, and closed for trees (from Fig. 2 of Bazzaz, *Ecology*, **56**, 487; 1975).

shows the classic lognormal distribution; when polluted, the community typically shows a pattern in which a few species become exceptionally common, with a hierarchical geometric series distribution (possibly caused by an early successional type of r-selection for success in handling the all-important new factor). Closer analysis may, or may not, reveal a lognormal distribution of relatively rare species hanging on down in the tail of the distribution.

These connections between patterns of relative abundance and degree of pollution have sparked off interest in the possibility of using some index of diversity to measure how much an ecosystem has been perturbed by human activity. One such attempt, using a diversity index as a phenomenological measure of gross toxicity in San Francisco Bay, is due to Anderson *et al.* (*Proceedings of 5th International Conference on Water Pollution Research,* Pergamon; 1971). Clearly, an engineering-style index of this kind would simplify tasks of environmental management. But Patrick (private communication) emphasises that, for her diatom communities in polluted streams, any such single number will be dominated by the geometric distribution of the common species, whereas the time scale for recovery of the pristine ecosystem (and, indeed, whether it can ever recover) depends on the lognormal tail of species which are uncommon in the polluted community, and whose presence will not show up in any overall diversity index. This amounts to a cogent argument (similar to that advanced by Williamson, in *The Mathematical Theory of Biological Populations,* Academic Press, New York, 1973) for describing the community by its full distribution of species relative abundance, and not trying to condense information into a single diversity index, which may mislead. The whole subject has practical importance for environmental impact studies, and deserves more attention than it has received to date. □

Earthquake prediction in China

from David Davies

IN March 1966 two severe earthquakes struck Hopeh Province, China; the scene of the disaster (relatively close to Peking) was visited by Chou En-Lai in his capacity as Prime Minister. Fortuitously the early part of 1966 also saw the start of the Great Proletarian Cultural Revolution. Earthquakes in China had caused great loss of life throughout history (nearly a million people died from one in 1556); what more logical project for a rebuilt people-oriented science programme than to attempt to predict earthquakes. And what more logical approach to this problem than to involve the general public as intensively as possible.

Nearly ten years later the fruits of this remarkable enterprise are beginning to become visible to Western eyes. In the November issue of *Eos,* the Transactions of the American Geophysical Union, is presented an extensive report of the American Seismology Delegation of October 1974 to China. Coincidentally, travellers' tales from more recent visitors to China begin to confirm the successful prediction of a very large earthquake on February 4, 1975—a prediction that may well have saved many thousand lives.

China does not fit simply into the scheme of plate tectonics. Scattered continental seismicity did not lend itself to the drawing of unambiguous plate boundaries, and it has taken several years to integrate what is known about surface geology, broad-scale lineations, earthquake distributions and their focal mechanisms into a reasonable tectonic synthesis. The work of Molnar and Tapponnier (*Science,* **189,** 419–426; 1975) suggests, for instance, that much of the seismicity in China can be considered as a result of the taking up of the convergence of the Indian subcontinent on Eurasia at a rate of 5 cm per year, with the concomitant necessity for parts of Eurasia to slide laterally out of the way. One of China's enormous assets is an earthquake record of sorts which goes back 3,000 years. North China in particular, has a record which the delegation called 'remarkably complete' for large events since 466 BC, and homogeneous for even small (magnitude 5) events since 1484 AD. The group noted that comparable dates for southern California would be 1850 and 1930. And yet even with this quality of reporting the patterns still remain complex, and as a result any programme of vigilance has to cover a substantial area of the country.

Ten thousand professionals participate in the Chinese earthquake programme, ten times the number in the United States, and there is a band of many thousand amateurs. Activity is spread widely over the country and the instrumental content of the programme is equally broadly based. Work is being conducted on all types of premonitory symptoms studied in the West—seismic, geodetic, electromagnetic, geochemical, magnetotelluric; and in addition there is considerable interest in acoustic precursors (earthquake sounds) and the unusual behaviour of animals. These last two phenomena have had a very shadowy history in the West—there is practically no scientist concerned about his professional reputation who would have ventured to express enthusiasm for them. But in China, where everyone is encouraged to report unusual events, there is a much greater interest in such possibilities.

Despite the encouragement of central government to pursue science for the people, it took five years from 1966 before the nationwide programme began in earnest. The turmoil at the Academy of Sciences during the cultural revolution must have been one major factor, as there was obviously a lack of steady central administration. Another factor must undoubtedly have been inadequate practical experience amongst geophysicists; the legendary ability of the Chinese has been to solve theoretical problems. Since 1971, however, the programme has developed enough confidence to issue at least eleven predictions which have led to extensive evacuations of threatened regions. Precise details both of the success rate and of the total data sets used have not been released, but there is no doubt at all that there have been major successes.

Ironically three months after the delegation had left China the most spectacular prediction came, for which, as yet, we have only the reports of more recent visitors. It seems that Liaoning Province had for several years been viewed as a possible target for a major earthquake as a result of migration of seismicity, and in the months before the quake, tilting occurred and there were observations of changes in well levels, telluric currents and animal behaviour. Then immediately before the magnitude 7.3 event, foreshocks gave sufficient warning for mass evacuations. There was enormous damage—a town of 100,000 is being completely rebuilt—but few fatalities.

Satisfaction at this major success must be tempered with some concern over the way in which the work will now advance. One of the disturbing themes running through the American delegation's report is an apparent weakness in more basic fields of research. The pendulum seems to have swung so far from theory that it is questionable whether there is adequate work going into the fundamental understanding of the processes that are being observed. Visitors speak of a far too ready acceptance of the work of any and everybody without the profound criticism that advances science most rapidly.

The successes of the Chinese programme come at a particularly crucial stage in the development of the United States project under the auspices of the Geological Survey. Recently an increasing amount of attention has been paid to the public policy aspects of prediction with, at least in some people's opinion, a concomitant build up in the public expectation that scientists are going to be able to deliver the goods in the very near future. Yet many seismologists privately entertain serious doubts that the premonitory symptoms are anything like unambiguous enough to warrant going public for some years to come. Three weeks ago Dr V. E. McKelvey, Director of the Geological Survey, was saying at a conference on earthquake warning and response, 'we are now entering an age when scientific instruments are detecting geophysical signals that can be interpreted to forecast earthquake occurrence'. Many would have preferred him to have put this age five or ten years in the future while some very difficult work is being done. Unfortunately, although the Chinese results are very exciting indeed, they may give the false impression that the United States is in for a similar pay off. This is rather unlikely. Foreshocks, the means by which the Chinese pinned down the time of the quake so accurately, are a relatively rare occurrence before major events, and other techniques used such as telluric currents, migration of seismicity and radon levels in ground water have yet to show their usefulness in the United States.

One thing is indisputable, however. The Chinese work will have acted as a shot in the arm to seismologists in all other countries engaged in prediction research. And by all accounts there is more excitement still to come. □

Messengers in minicells

from M. R. Blundell

THE first experiments demonstrating the existence of messenger RNA in bacteria were published in 1961. One of the criteria for identification of mRNA was its short lifetime, which permits a rapid halt in synthesis of a specific protein, but our knowledge of the processes responsible for inactivation and degradation of mRNA remains very incomplete fourteen years later.

We know that degradation proceeds from the 5′ to the 3′ end of mRNA (Morikawa and Imamoto, *Nature*, **223**, 37, 1969) but it is clear that the 5′-exonuclease activity called ribonuclease V (Kuwano, *et al.*, *J. molec. Biol.*, **51**, 75; 1970) cannot be responsible alone for mRNA degradation (Imamoto and Schlessinger, *Molec, gen. Genet.*, **135**, 29; 1974).

What was regarded as merely a scavenging process has taken on new significance with the discovery that individual messages in the same *Escherichia coli* cell can have different decay rates with half-lives ranging from 40 s upwards at 37 °C (Marrs and Yanofsky, *Nature new Biol.*, **234**, 168; 1971; Blundell *et al.*, *Nature new Biol.*, **238**, 46; 1972; Craig, *et al.*, *J. molec Biol.*, **71**, 701; 1972, and others). Even messages in the same polycistronic mRNA can have quite different decay rates.

Hirashima, Childs and Inouye (*J. molec. Biol.*, **79**, 373; 1973) discovered a message with a particularly long functional half-life, 11.5 min at 37 °C, which codes for a low molecular weight lipoprotein of the outer membrane of *E. coli.* Both *et al.* (*J. molec. Biol.*, **67**, 199; 1972) presented measurements of the secretion of an extracellular protease by *Bacillus amyloliquefaciens* which could be interpreted in terms of a mRNA stable for up to 80 min at 30 °C, but subsequently, they concluded (Glenn *et al*, *J. molec. Biol.*, **73**, 221; 1973) that this message was not especially stable, but was instead made in very large quantities. In hybridisation experiments, however, Brown and Coleman (*J. molec. Biol.*, **96**, 345; 1975) could not find such quantities of mRNA, or any especially stable mRNA in cultures of *B. amyloliquefaciens.*

Now Levy (*Proc. natn. Acad. Sci. U.S A* , **72**, 2900; 1975) reports the presence of a small quantity of very long lived mRNA in *E. coli* minicells, structures about one tenth the size of whole cells which are made in abnormal cell divisions of an *E. coli* mutant and lack the *E. coli* chromosome. Plasmid DNA that segregates into minicells is transcribed and translated, but plasmid-less minicells do not make DNA or RNA. Levy observes, however, that ^{35}S-methionine is incorporated by freshly isolated minicells into hot trichloroacetic acid precipitable material at 0.2 to 0.5% of the rate in whole cells. The incorporation is sensitive to chloramphenicol, so it is presumably ribosomal polypeptide synthesis. Protein synthesis decays during incubation at 37 °C with a half-life of about 80 min, and is unaffected by rifamycin. The major products of protein synthesis in plasmid-free minicells are four polypeptides of the outer cell membrane, one of these being the lipoprotein coded by the long lived mRNA studied by Hirashima *et al*

We can, therefore ask, as does Levy, why the messages for membrane proteins should be so stable in minicells. Minicells containing an R factor continue to make short lived mRNA which codes for other proteins, so mRNA can be degraded in minicells, but no comparison of the decay rates of R factor messages in whole cells and minicells is presented. One possibility, since minicells form from the poles of cells, is that the cell extremities, and therefore minicells, are relatively deficient in specific nuclease(s).

We may also ask why membrane proteins should have abnormally stable message. To investigate this question Hirashima, Wang and Inouye are now developing a cell-free translation system which synthesises the lipoprotein when purified mRNA is added. □

Unexpected proviruses in chronic infection

from Robin Weiss

RECENT reports by Zhdanov (*Nature*, **256**, 471; 1975) and by Simpson and Iinuma (*Proc. natn. Acad. Sci. U.S.A.*, **72**, 3230; 1975) promise to open up a new area of genetic exchange between RNA viruses and their hosts. These authors claim that some animal RNA viruses that conventionally replicate by means of RNA intermediates can under conditions of chronic infection form DNA "proviruses".

Simpson and Iinuma have studied a temperature sensitive mutant of respiratory syncytial (RS) virus in bovine embryo kidney (BEK) cells infected and maintained at the non-permissive temperature of 39 °C. These BEK/RS cells did not release RS virus or synthesise RS viral antigens detectable by immunofluorescence. However, even late passage cultures yielded infectious virus when co-cultivated with uninfected cells or when treated with agents such as halogenated pyrimidines. These findings led the authors to look for DNA proviruses of RS virus using transfection techniques as described by Hill and Hillova (*Nature new Biol.*, **231**, 261; 1971) for the provirus of Rous sarcoma virus. When HEp-2 cells were treated with DNA extracted from the BEK/RS cell line infectious RS virus was recovered. A clonal analysis of the progeny RS virus indicated that some clones retained the special properties of the virus that initiated the chronic infection—temperature-sensitive replication and heat-resistant virions—whereas other clones had lost one or both of these properties and more closely resembled wild-type RS virus. Simpson and Iinuma further showed that a chronically-infected cell line of HEp-2 cells, survivors of an infection with wild-type RS virus, similarly contained infectious DNA for RS virus.

Zhdanov's analysis is less detailed but wider ranging, and illustrates the same phenomenon of DNA provirus formation in cultures chronically infected with RNA viruses. Persistent infections were established with measles virus in chick embryo cells, Sindbis virus in murine L cells and tick-borne encephalitis virus in HEp-2 cells. Using tritiated viral RNA, Zhdanov showed by hybridisation C_0t analysis that the chronically infected cells in each of the three systems contained sequences homologous to the viral RNA, whereas the uninfected control cells did not. With the chronically infected HEp-2 cells he was also able to recover infectious tick-borne encephalitis virus by DNA transfection.

The formation of proviruses demands transcription of RNA to DNA and both groups found 'reverse transcriptase' activity associated with the chronically infected cells. Zhdanov assumes that the persistently infecting virus interacts with latent oncornaviruses present in the cultures. It will be interesting to determine whether the presence of oncornavirus reverse transcriptase is necessary for provirus formation, and whether the provirus is a prerequisite to or a consequence of the development of such persistent infections. What is remarkable is that not only are some DNA sequences transcribed, but whole, transfectable proviruses are formed, suggesting a process of orderly, complete reverse transcription. Simpson and Iinuma also comment in their discussion that plaque-purified RS virus recovered from DNA transfection carries reverse transcriptase activity and may represent recombinant virus species. One wonders, therefore, whether other lytic viruses which replicate by way of a DNA provirus, such as visna virus and avian reticuloendotheliosis virus, might have evolved in a similar way and might possess alternative modes of replication.

These studies raise interesting questions not only for molecular biologists but also for students of persistent infections and 'slow' virus diseases. Zhdanov presents evidence for measles virus DNA in tissues of patients suffering from systemic lupus erythematosus. No doubt the hunt is on for DNA copies in other 'viral' autoimmune diseases. □

Martian canals after Mariner 9

from David W. Hughes

EVER since 1877 when Schiaparelli drew attention to the existence of canals on Mars they have been the subject of heated controversy and, at times, distinct embarrassment to planetary astronomers. Mariner 9, the spacecraft that went into orbit around Mars in 1971, achieved a complete mapping of the surface down to a resolution of 1 km, so now the question, "where are the canals?" should be answerable. Sagan and Fox of the Laboratory for Planetary Studies, Cornell apply themselves to this question in a recent issue of *Icarus* (**25**, 602; 1975).

Many suggestions have been put forward to explain the observations, observations which cannot be discounted out of hand, because, even though the features are of intrinsically low contrast and small angular size usually observed under poor seeing conditions, many maps of tolerable mutual consistency have been produced by different astronomers.

Canals have been thought to be waterways or the vegetation along the banks of waterways constructed by an advanced civilisation. Natural valleys, surface cracks or ridges produced by a range of geological processes were another suggestion. Accidental alignments of surface features (for example chains of large craters) was a third. They may also be rectilinear sand dunes or dark rays emanating from craters, or simply albedo features, regions of differing reflectivity that are periodically covered and uncovered by windblown dust.

Sagan and Fox compare the Mariner 9 results with the canal cartography of Slipher (*Mars,* Sky Publishing Co., Cambridge, Mass; 1962). A striking correlation was found between the canal Agathodaemon and the great rift valley Valles Marineris but as the latter is a low albedo feature 5,000 km long and 100 km wide it is only to be expected that this is easily resolvable by ground-based observers. Thoth-Nepenthes is also easily discernible on both maps as is the ridge Ceraunius.

Returning to the hypotheses concerning canal origin, Sagan and Fox conclude that the resolution and surface cover of Mariner 9 would have detected a civilisation like Earth's if it had been present on Mars. Correspondences do occur between classical canals and valleys or ridges, Agathodaemon-Valles Marineris has been mentioned and Styx-Phlegra Montes and Ceraunius are other examples. Psychophysiological alignments of disconnected fine detail only seem probable in the case of the canal Oxia which seems to be the chain of craters Trouvelot, Rutherford, Becquerel, Curie and Sklodowska and an unnamed canal which goes through craters Galle, Wirtz, Helmholtz and Lohse. Very few crater rays were seen by Mariner 9 and sand dune fields do not seem to be sufficiently extensive to be observed from Earth. A few canals notably Cerberus and Thoth-Nepenthes do correspond to dark features on the Martian surface, these features being unconnected to topography. They might, however, be regions where fine bright dust does not settle or regions where the ground is dark due to surface roughness or some geochemical reason.

While a few canals do correspond to topographic and albedo features on Mars, Sagan and Fox conclude that the large majority of canals do not. Conversely there are many real surface features, for example large shield volcanoes like Olympus Mons, Arsia Mons and Pavonis Mons, where no canals were marked on the maps.

Sagan and Fox discount the canal observations and relegate them to monuments to the imprecision of the human eye labouring under difficult seeing conditions. But does the story really end here. Probably so, but the consistency of the diverse maps leaves a lingering unease. Maybe the facts that Mariner 9 could not distinguish between features which had less than 5% albedo contrast, that Mars was only observed for half a Martian year, or the violent dust storms that preceded Mariner 9's visit caused the real truth to be hidden. □

Parity determination with polarised deuterons

from P. E. Hodgson

A NEW technique for determining the parity of nuclear states has been developed recently by Kuehner *et al.* (*Phys. Rev. Lett*, **35**, 423; 1975) at McMaster University, Hamilton, Ontario. The method depends on the properties of the coupling between the orbital and spin angular momentum vectors in the initial and final states. In certain conditions the yield of particles from a reaction at 0° (or 180°) on an even-even target is zero for states of natural parity $(-)^J$, so a single measurement determines the parity if the spin J of the state is known.

The conditions for this to hold are that the magnetic quantum numbers m are zero in the initial and final states. Since these are the z-components of angular momenta (taking the beam direction as the axis of quantisation) this may be ensured by using a polarised incident beam with $m=0$ and detecting the products of the reaction along the beam axis, that is at 0° or 180°. Nucleons have $m=\pm\frac{1}{2}$, and so cannot be used, but deuterons having spin one can be in the $m=0$ or ± 1 states, and it is possible to polarise the beams.

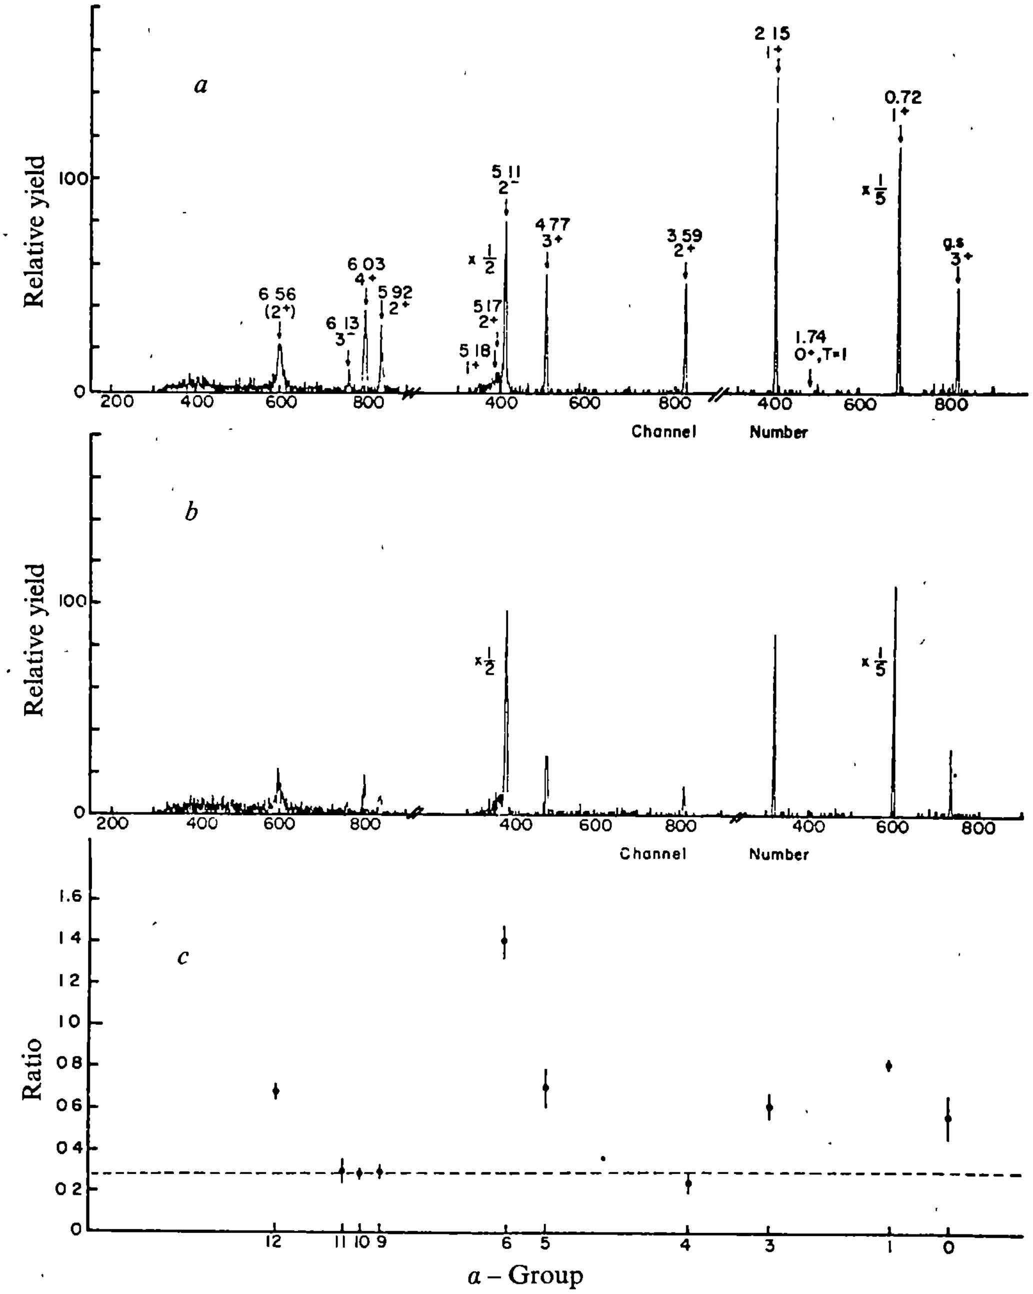
Although this method is simple in principle, it is not simple to carry out in practice. It is difficult to produce polarised beams, and existing techniques cannot yet give 100% polarisation. It is therefore necessary to compare the results of measurements with unpolarised and partially polarised beams. It is also difficult to make measurements very near to 0°, but a subsidiary study showed that in practice the intensities of the forbidden reactions are very low below 2°, and so measurements made at this angle are sufficiently good.

Kuehner *et al.* applied this technique to the reaction $^{12}C(d,\alpha)\ ^{10}B$, and some of their results are shown in the figure. The upper spectrum was obtained with an unpolarised beam and the lower with a partially polarised beam. It is immediately evident that the relative intensities are different, and the actual ratios are also displayed. The intensities of the states with parity $(-)^J$ are most strongly reduced, though not to zero, because of the residual $m=\pm1$ components in the partially polarised beam. A subsidiary calculation shows that these states should be reduced by the ratio indicated by the dashed line in the figure.

These ratios therefore give immediately the parity of the final state of ^{10}B: those with ratios on the dashed line have parity $(-)^J$ and those with ratios above the line have parity $(-)^{J+1}$. Since the spins are usually known, this gives the required parities. There may be some cases where the parity is known and the spin from other measurements must have either of two consecutive values; in this case the method determines the spin.

An example of this latter situation is provided by the state of ^{10}B at 6.56 MeV. Previous measurements had indicated 2^+, though 3^+ was also a possibility. The measurements of Kuehner *et al.* show that the spin must be odd, and thus the assignment 3^+ is confirmed.

This new technique should prove a powerful way of determining the parities or spins of nuclear states. If both the spin and the parity are known, it can be also used to determine the tensor polarisation of a beam of spin-one particles; this could be particularly useful for projectiles like ^6Li for which the usual double-scattering method is difficult. □



Spectra of alpha-particles from the reaction $^{12}C(d,\alpha)\ ^{10}B$ at 2° to the incident beam for an unpolarised (*a*) and for a partially polarised beam. (*b*) Also shown (*c*) is the ratio of the intensities for the two cases; this has the value shown by the dashed line for states with parity $(-)^J$ and a higher value with states with parity $(-)^{J+1}$.

Seed dispersal

from Peter D. Moore

SEED production, seed germination and seedling establishment are, for most plant species, critical stages in the maintenance of population levels. The quantity of seed produced and the energy reserve of each individual seed vary from one species to another;

Harper, *et al.* (*A. Rev. ecol. Syst.*, **1**, 327; 1970) pointed out that r-selected species often produce large quantities of small seeds whereas K-selected ones often have a small number of large seeds. Survival of seeds depends upon the avoidance of predation, and numerous mechanisms have evolved by which such avoidance may be effected, for example by toxicity or by rapid and widespread dispersal (Janzen, *Evolution*, **23**, 1; 1969). The scattering of seeds besides reducing the risks of predation, also assists the avoidance of intra-specific competition among seedlings and permits the spread of the species to new localities, thus aiding the exchange of genetic material.

A recent study of seed production and dispersal in the genus *Viola* by Beattie and Lyons (*Am. J. Bot.*, **62**, 714; 1975), illustrates the complex results produced by these interacting selective pressures. Initial studies of seed dispersal in the genus led to the classification of *Viola* species into two major groups, one myrmecochorous (dispersed by ants) and the other diplochorous (explosively ejected from the capsule and subsequently further transported by ants). Diplochorous types have many morphological features associated with projectile dispersal, such as an erect, tall peduncle to the capsule and a relatively small caruncle on the seed when compared with the myrmecochorous types. The explosive ejection of these seeds often results in their being thrown 1·5 m from the parent plant.

The possession of a caruncle by the diplochorus types suggests that there is a subsequent stage in dispersal when the caruncle may serve as an attractant and a food reserve for the transporting agent. If this were not so, then selection would presumably have resulted in the loss of the caruncle in these species in the interest of aerodynamics. To examine this, Beattie and Lyons placed different types of *Viola* seed in areas of woodland in West Virginia and also in prairie in Illinois where ant nests were abundant. The diplochorous seeds were collected by ants when fresh whether they were placed in groups or scattered as individuals, but the rate of collection was considerably lower if seeds from the previous season were used. Evidently their attractiveness to ants is adequate while they are fresh, but deteriorates with age.

In the case of the myrmecochorous types, only old seed was available. These were placed in groups to simulate the natural situation when such seeds would remain in their capsules. It was found that the rate of disappearance was as rapid for these old seeds as in the case of the fresh diplochorous seeds. The myrmecochorous types evidently have mechanisms of attraction which are more persistent than those of the diplochorous types.

The myrmecochorous types have evolved a dispersal strategy in which they combine tough seed coats, easily accessible energy-rich seeds located in groups, with a frequent recurrent production of new seeds. The danger of such a strategy lies in the close grouping of the seeds, which exposes them to predation, and this is overcome by the development of mutualistic relationships with specific ant species. These ants collect the seeds regularly from predictable localities and carry them to their nests where they feed upon the caruncle, leaving the embryo unharmed and able to germinate. Predation avoidance is thus dependent upon collection and dispersal by ants. The heavy seeds and large, energy-rich caruncles of these species assist in the strategy, which can be considered as an essentially K-selected one.

The diplochorus mechanism provides an alternative solution to the dangers of seed predation. Local concentrations of seeds are avoided by the explosive dispersal mechanism, but the retention of the caruncle ensures that the seeds will be found and further dispersed by ants. In the experiments, almost all fresh diplochorous seeds had been found and removed within three days. Beattie and Lyons suggest that full dependence on ant dispersal is only possible in situations where an ant species with the appropriate behaviour pattern is abundant. In sites with depauperate ant faunas, the diplochorous strategy is more reliable. This may account for the geographical restriction of the myrmecochorous *Viola* species to those regions of Eurasia where the mound-building, scent-trail laying ant species *Formica rufa* is found. □

Fishing for complement

from Robin Hesketh

THE study of the movement of protein complexes in the plane of the fluid membrane has kept a good many immunologists off the streets since the demonstration in 1971 by Taylor, Duffus, Raff and de Petris of the redistribution of lymphocyte surface immunoglobulin molecules after their interaction with antibody It now seems that a venerable method for measuring the binding (fixing) of complement (C) by antigen–antibody complexes may assist in defining the necessary environment for membrane receptors to participate in some immunological reactions.

It is now well known that the fluidity of membranes can be changed by varying the amount of cholesterol present, and Humphries and McConnell (*Proc. natn. Acad. Sci. U.S.A.*, **72**, 2483, 1975) have used this fact to correlate the lateral mobility of a membrane antigen with its C-fixing ability.

As a model membrane they used a lecithin bilayer containing cholesterol into which the monovalent lipid antigen cardiolipin had been introduced. Complement binding by this system in the presence of human syphilitic serum, which contains antibodies against cardiolipin, provides one of the simplest models for immune cytotoxic attack.

This system of lipid suspensions, later christened liposomes, was first developed by Osler and Knipp (*J. Immun.*, **78**, 19; 1957) in a search for a precise method for estimating the cardiolipin-specific Wasserman antibody in human syphilitic serum. They showed that the low antigenic activity of suspensions of monovalent cardiolipin was greatly enhanced by the addition of lecithin, and that maximum precipitation of antibody occurred when cardiolipin was present with lecithin and cholesterol.

In measuring C fixation, Osler and Knipp showed that rabbit or human syphilitic sera yielded identical reaction curves with three different mammalian cardiolipins, and that dimyristoyl lecithin could substitute for beef heart lecithin in the liposome without reducing its ability to bind IgM and C. They also showed that the lecithins alone had very little anti-complementary activity.

Using dimyristoyl or dipalmitoyl lecithin in the cardiolipin-sensitised lipsome system of Osler and Knipp, Humphries and McConnell found that the degree of C fixation increases with the rigidity of the membrane (that is, with cholesterol concentration). A minimum cholesterol content of 35 mol %, however, is required to initiate significant C consumption. It is known from X-ray diffraction and differential scanning calorimetry that phospholipid/cholesterol interaction is maximal at 33 mol %—greater cholesterol concentrations creating cholesterol–cholesterol contacts within the membrane. Humphries and McConnell have used electron spin resonance methods to construct a phase diagram for the lipid systems used which indicates that at greater than 35 mol % cholesterol the cardiolipin becomes strongly immobilised and probably laterally segregated—either in an environment consisting entirely of cholesterol or incorporated in a solid phase of the membrane. The authors suggest that cardiolipin 'receptors' in this state may be able to bind several of the sites on an IgM molecule. thereby distorting the structure of the antibody in the manner required to accommodate the first component of the complement sequence. This conforms with the hypothesis of C fixation by IgM propounded by Ishizaka and Ishizaka (*J. Immun.*, **102**, 1337; 1969) and supported by electron micrographs of 19S haemolytic antibodies forming loops to bind to nearby sites on a single erythrocyte membrane (Humphrey and Dourmashkin, *Ciba Foundation Symposium on Complement*, 1965).

Returning to the wider implications of their work, Humphries and McConnell, although aware of course that submembranous structures as well as lipid composition are involved in protein mobility in membranes, observe that the conditions of hapten mobility which they find necessary for C-mediated cytotoxic attack may also apply to direct lymphocyte stimulation by these liposomes. As evidence for this they point out that haptens stimulate an immunological response only when they are bound to a protein carrier. Such intriguing parallels will no doubt leave cellular immunologists asking how long it will be before the complementary experiments of manipulating the composition and hence the mobility or function of receptors is accomplished in a living cell. ☐

Circadian rhythms

by Miranda Robertson

The Dahlem Workshop on the Molecular Basis of Circadian Rhythms was held in West Berlin on November 3–7.

With a field in the state that prevails in research on circadian rhythms, the particular format of the Dahlem Konferenzen should have proved an interesting experiment. The Workshops, of which this was the third, are explicitly designed to define the most important problems in a given field and to suggest fruitful directions for further research. Most of the conference time is spent in discussion: instead of being formally presented, background papers are written by and distributed to participants before the beginning of the meeting, and by the end, the members of each of six small groups have been forced into some kind of agreement in the production of a group report on their conclusions.

Agreement is a rare commodity in this field, whose present state has been compared (optimistically?) with that of Mendelian genetics before the discovery of the genetic code in the sense that the "hard" data are phenomenological. It is now very well established that numerous physiological processes, from photosynthesis in plants to motor activity in mammals, have an autonomous more-or-less 24-hour cycle which can be synchronised with the diurnal light-dark cycle by entrainment. The phenomenology has been enormously extended in experiments on how the various rhythms respond to changes in the phase or the period of the entraining cycle (the Zeitgeber). The task of the workshop participants was to decide on a strategy for discovering what cellular mechanism might give rise to oscillations with the observed characteristics. A group of mathematical modellers tried to decide what those characteristics say about how the clock works in principle and concluded that it is still impossible to distinguish between mechanisms as simple as the "dripping faucet" and as sophisticated as a limit cycle. Indeed, in general the field suffers from a surfeit of models and a dearth of critical experiments Three categories of nonmathematical model were represented: enzyme models, genetic models and membrane models. The evidence in favour of any of them however tended to be somewhat general: substances which, say, disrupt protein synthesis or alter membrane characteristics sometimes disrupt the circadian rhythm one way or another.

One serious problem facing genetic and membrane modellers is that neither genetic regulation nor membrane function is properly understood in eukaryotic cells.
